Between perennial or constant springs, and those which are merely dependent on the last shower of rain, the gradations are insensible, and the explanation is entirely obvious upon the general principles stated. One of the most interesting cases of this intermediate series, is that of the "intermitting" springs. It is a common circumstance on the chalk downs of the South of England (Wiltshire, Dorsetshire) for the valleys to be quite dry in one part of the year (autumn or winter), and very fully watered in another (spring, summer); the springs bursting higher up the valley in some years than in others, according to the quantity of rain which fell in some previous season (as the autumn), and the rate of its transmission through the jointed and absorbent chalk.

Another peculiarity of springs flowing out of cavernous limestone rocks is marked by a variable discharge; the springs now gush with vehemence, now subside, shrink away, and disappear. These ebbing and flowing wells are noticed in many districts, as near Dynevor in Caermarthenshire, at Tideswell in Derbyshire, and near Settle in Yorkshire. The explanation most generally received supposes the water to fill cavities underground, from which the discharging channels are siphon-formed, so that at a particular moment the full cavity begins to be discharged and finally runs out, and the current then ceases till the space be again filled to the vertex of the siphon-formed arch.

In thus descending downwards and rising upwards through various mineral masses, springs become impregnated with gaseous, saline, earthy, or metallic admixtures—as carbonic acid gas, sulphuretted hydrogen gas, nitrogen, muriate of soda, sulphate of lime, carbonate of lime, silica, carbonate of iron, &c. [ARTESIAN WELL; WATERS, MINERAL.]

SPRINGS, MINERAL. [WATERS, MINERAL.]

SPY. In the discussion of this and many other questions of international law the terms Right, Law, Lawful, and others of the same class, must be understood in a different sense from their proper technical meaning. What writers on international law speak of as a Right is very often merely what appears fair, reasonable, or expedient to be done, or to be permitted. It is this reasonableness or expediency alone which is the foundation of those various usages which are recognised by independent civilised nations in their intercourse among one another, and constitute what is called the Law of Nations. Thus a person or a power is said to have a right according to the Law of Nations, which means that the usage of civilised nations permits the act, and this is the least objectionable sense in which the word Right is used.

No doubt, we believe, has ever been intimated by any writer of authority on International Law, as to the right of nations at war with each other to avail themselves of the service of spies, or secret emissaries, in carrying on their hostile operations; and still more expressly is the general right of employing spies conceded to every conductor of military operations; but it is equally admitted that spies when caught by the enemy may be hung, and such is their usual fate. Vattel says, "A man of honour always declines serving as a spy, as well from his reluctance to expose himself to this chance of an ignominious death, as because, moreover, the office cannot be performed without some degree of treachery." In ordinary cases, he adds, "the general must be left to procure spies in the best way he can, by tempting mercenary souls by rewards."

The employment of spies is conceived to be subject to certain limitations in respect to the manner of it and the object attempted to be gained by it. "We may lawfully endeavour," says Vattel, "to weaken the enemy by all possible means, provided they do not affect the common safety of human society, as do poison and assassination." Accordingly the proper business of a spy is merely to obtain intelligence, and such secret emissaries must not be employed to take the lives of any of the enemy, although that, done in another way, is commonly the main immediate object of the war. Yet it might be somewhat difficult to establish a clear distinction between what would be called an act of assassination by a spy, and many of those surprises of an enemy which, so far from being condemned or deemed dishonourable to the actors, have usually been admired. A distinction however has been taken; and it has been maintained that an officer or soldier cannot be treated as a spy if he had his uniform on when apprehended. See Martens 'Précis du Droit des Gens Modernes de l'Europe' (traduit de l'Allemand), Paris, 1831, liv. viii., ch. iv., § 274; where references are made to Bruckner, 'De Explorationibus et Exploratoribus,' Jen., 1700; to Hannov., 'Gel. Anzeigen,' 1751, pp. 383 et seq.; and, in regard to the celebrated case of André in the American war, to Martens, 'Erzählungen merkwürdiger Fälle,' i. 303; and to Kamptz, 'Beyträge zum Staats und Völkerrecht,' tom. 1., No. 3.

A question closely connected with the so-called lawfulness of employing spies, and indeed forming in one view a part of that question, is that of the lawfulness of soliciting the enemy's subjects to act as spies, or to betray him. Such measures, says Vattel, are practised in all wars, but they are not honourable nor compatible with the laws of a pure conscience. "If such practices," he concludes, "are at all excusable, it can be only in a very just war, and when the immediate object is to save our country when threatened with ruin by a lawless conqueror. On such an occasion (as it should seem) the guilt of the subject or general who should betray his sovereign when engaged in an evidently unjust cause would not be of so very odious a nature." But who ever heard of a war that was not thought by those engaged in it to be a just war on their own side and an unjust war on the part of their adversaries? So that this distinction settles nothing. It is held, however, to be perfectly allowable in every point of view merely to accept the offers of a traitor.

The proper question as to the so-called law of nations with regard to spies, is what practices are sanctioned by the general usage of independent civilised nations. Such practices as are now permitted by such usage constitute a part of this so-called international law. Those practices which are not generally permitted or acknowledged are not yet a part of such law. Persons who have occasion to write or think on this subject will find that much of the indistinctness and confusion observable in the treatises on the law of nations will be removed if they will first form for themselves a clear conception of the proper meaning of the word Law, and of the improper meanings which it has also acquired; and they will thus be enabled to give the necessary precision to those terms which are used so vaguely by writers on international law. [LAW; RIGHT.]

SQUADRON is supposed to be derived from "squadra" (Italian), which is itself corrupted from the Latin word "quadratum;" acies quadrata denoted a body of men drawn up in a square form. The term "escadron" occurs in Froissart's 'Chronicles,' and probably it was very early used in the French armies to designate a body of cavalry. It is generally used to designate a part of a fleet, or even of an army. Milton speaks of 'squadron'd' angels. Technically, however, it means the principal division of a regiment of cavalry, which is divided into two troops, each of which is commanded by its captain, who has under him a lieutenant and a cornet.

The strength of an army, with respect to cavalry, is usually expressed by the number of squadrons in the field, as it is with respect to infantry by the number of battalions.

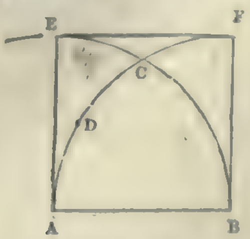
For the manner in which a regiment of cavalry is encamped, see ENCAMPMENT.

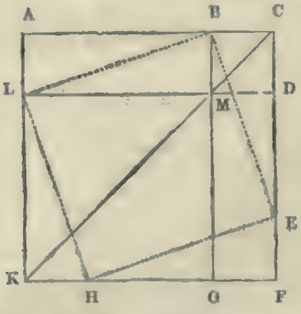
SQUARE. We believe that the old English meaning of this word had reference only to the corners of a figure, or at most to right-angled corners. The old word for any oblong, or rectangle, is a *four-square* figure; the carpenter's rule for drawing a right angle is called a T-square to this day. The French word *équerre* (anciently *esquerre*, originally derived, like the Italian *squadra*, from *quadratum*) is the immediate origin; and this (in French) means also an instrument for drawing a right angle. In Recorde's 'Ground of Arts,' the earliest English geometry extant, he calls what is now a square by the name of *square quadrate* (*square*, right-angled, *quadrate*, four-sided figure); and it is not until he is considerably advanced in his work that he seems to find out that he may drop the second word and retain the first only. There was still an incorrectness, for a square figure should have meant one having all its angles right angles; that is, what we now call a rectangle, whether its sides were equal or not. To complete the proof of connection between the square and the right-angled corner, we may mention that before now a right-angled *triangle* has been called a *square*. In or about 1613, Thomas Bedwell published a work, of which the title was '*Trigonum* Architectonicum, the Carpenter's Squire.'

In geometry, a square means a four-sided plane figure with all its sides equal, and all its angles right angles. In algebra, it signifies the number produced by multiplying a number by itself. The reason of the double meaning is obvious enough. [RECTANGLE.] A square of 7 units long contains 7×7 square units; so that the operation 7×7 is the arithmetic of finding the content of a square of 7 units in length and breadth. We have spoken, in the article just cited, of the confusion which is caused by this double use of the word square; and proposed to correct it by speaking of the square *on* a line in geometry, and the square *of* a number in algebra. It has been the fashion of late years to publish what are called *symbolical* editions of Euclid, in which AB^2 is made to stand for the square *on* the line AB, because a^2 stands for the square *of* the number a. The learner who uses this species of symbol will not, without great care, avoid false reasoning in making the connection between geometry and algebra.

A square is divided by its diagonal into two isosceles right-angled triangles: its diagonals are equal, and bisect each other at right angles. The easiest way of drawing a square is to describe two circles on the side A B, and bisecting A C in D, to make C E and C F equal to A D; the figure A E F B is then a square.

Of all similar figures, squares are those to the areas of which reasoning is most easily applied. If three similar figures be described on the sides of a right-angled triangle, the sum of those on the sides is equal to that on the hypothenuse. This proposition is learned with reference to squares [HYPOTHENUSE] long before it can be proved with reference to similar figures in general: the consequence is, that the general proposition is almost overlooked by the previous occurrence of the particular case. We have noted in the article just cited the Hindu proof of this celebrated case; the simplest properties of the square may be made to give a more easy proof, founded on the same principle; it being remembered that the first four propositions of the second book of Euclid do not require the last two of the first book. The proof is as follows:—Let A B, B C, be the sides of a right-angled triangle, and on their sum describe a square; make C E, F H, K L, each equal to A B. It is easily proved that L B E H is the square on the hypothenuse of the triangle; and it is made by subtracting four times the triangle from the whole square A F. But if four times the triangle be subtracted by taking away the rectangles A M and G D, we have (Euc., ii. 4) the sum of the squares on the sides, which is therefore the same as the square on the diagonal.





SQUARE ROOT, the name given to a number with reference to its square. Thus, 49 being the square of 7, 7 is the square root of 49. When an integer has no integer square root, it has no square root at all in finite terms: thus 2 has no square root. But since 1·4142136 multiplied by itself gives very nearly 2, or has a square very near to 2, it is customary to say that 1·4142136 is very nearly the square root of 2: more properly, the square root of something very near 2.

The extraction of the square root came into Europe with the Indian arithmetic, the method followed by Theon and other Greeks (which was substantially the same) having been forgotten. The earliest extensive treatise on the subject is that of P. A. Cataldi (Bologna, 1613), though the books of algebra and arithmetic had then been long in the habit of giving the rule. The process presently given for finding the square root of a number in a continued fraction was first given (in a less easy rule) by the same Cataldi, who was thus the first who used continued fractions. This fact was pointed out by M. Libri, before which Lord Brounker was generally considered as the first who used continued fractions.

The rule for the extraction of the square root is a tentative inverse process very much resembling division, and is contained under the general rule given in INVOLUTION AND EVOLUTION. The peculiar simplicity of this case, however, allows of a condensation of form, and makes the demonstration easy. The general rule just alluded to might be demonstrated on the same principle.

In order to turn the square of a into the square of $a+b$, we must add to the former $2ab+b^2$, or $(2a+b)b$. This follows from

$$(a+b)^2 = a^2 + 2ab + b^2.$$

An example will now show how the square root is extracted; first roughly, afterwards more skilfully in the choice of trials. Let the number be 104713. The square of 100 being 10000, which is much too small, we go on adding 100 to the square root, until no more hundreds can be added; all the while forming the squares by the rule, each square from the preceding. We then begin to add tens, forming the squares also, until the addition of one more ten would bring the square past 104713; we then add units, until either the square is exactly 104713, or the nearest to it. Or, instead of continual additions, we might subtract every number, as we get it, from 104713 until no more subtractions can be made. Both modes are exhibited in the following:—

$$\begin{array}{rr@{\qquad\qquad}r}
100^2 = & 10000 & 104713 \\
100\,(2 \times 100 + 100) = & \underline{30000} & \underline{10000} \\
200^2 = & 40000 & 94713\ a \\
100\,(2 \times 200 + 100) = & \underline{50000} & \underline{30000} \\
300^2 = & 90000 & 64713\ b \\
10\,(2 \times 300 + 10) = & \underline{6100} & \underline{50000} \\
310^2 = & 96100 & 14713\ c \\
10\,(2 \times 310 + 10) = & \underline{6300} & \underline{6100} \\
320^2 = & 102400 & 8613\ d \\
1\,(2 \times 320 + 1) = & \underline{641} & \underline{6300} \\
321^2 = & 103041 & 2313\ e \\
1\,(2 \times 321 + 1 = & \underline{643} & \underline{641} \\
322^2 = & 103684 & 1672\ f \\
1\,(2 \times 322 + 1) = & \underline{645} & \underline{643} \\
323^2 = & 104329 & 1029\ g \\
1\,(2 \times 323 + 1) = & \underline{647} & \underline{645} \\
324^2 = & 104976 & 384\ h
\end{array}$$

In the first column we feel our way, so to speak, by hundreds, by tens, and by units, up to the result that 323^2 is too small, and 324^2 too great; so that we see that 104713 has no square root. In the second column we go down from 104713, and subtracting the squares already formed in the first column, we come to the result that 104713 is 384 more than 323^2, but less than 324^2. The results of the second column are—

$$\begin{array}{r@{\qquad\qquad}r}
94713 = 104713 - 100^2 & 2313 = 104713 - 320^2 \\
64713 = 104713 - 200^2 & 1672 = 104713 - 321^2 \\
14713 = 104713 - 300^2 & 1029 = 104713 - 322^2 \\
8613 = 104713 - 310^2 & 384 = 104713 - 323^2
\end{array}$$

The best method of making the trials depends upon the following circumstances:—

1. A square number followed by an even number of ciphers, such as 16000000, is also a square number.

2. If $b\,(2a+b)$ is to be found as near as possible to R, and if $2a$ be considerable compared with b, the value of b is near to that given by $b \times 2a = \mathrm{R}$, or $b = \mathrm{R} \div 2a$.

Taking the number 104713, and parting it into periods of two numbers each, we have 10, 47, 13, and 9,00,00 is the highest square belonging to a simple unit followed by ciphers, which can be contained in it. Choose 300 for the first part of the root, and we have 14713 for the remainder. If b be the number of tens in the root, we have to make $10b\,(2 \times 300 + 10b)$ as near as we can to 14713, or $10b$ not being much compared with 600, we must try $10b \times 600 = 14713$, or $b = 14713 \div 6000$, whence 2 is the highest (perhaps too high, but that will be seen by the remainder). If $b=2$, $10b\,(600+10b)$ is 12400, which, subtracted from 14713, gives 2313. The part of the root now obtained is 320, and if c be the number of units, $c\,(2 \times 320 + c)$ must be made equal, or as near as can be, to 2313. Now c is very small compared with 640, and $c \times 640 = 2313$ shows that $c = 3$ at most, giving 3×643, or 1929, to be subtracted from 2313, which leaves 384. The process may be written thus:—

$$\begin{array}{rl}
 & 1\dot{0}4\dot{7}1\dot{3}\ (300 + 20 + 3 \\
 & \underline{90000} \\
600 & \big)\,14713 \\
20 & \big)\,\underline{12400} \\
640 & \big)\,2313 \\
3 & \big)\,\underline{1929} \\
 & 384
\end{array}$$

which, omitting superfluous ciphers, is the one commonly used. We do not intend to dwell on the common process, which is in all the books, but confine ourselves to the explanation, which is frequently omitted.

We now take a longer instance, at full length, followed by a statement of its results:—

```
             2̇90̇22̇52̇96̇ (10000
             100000000 \  7000
             ---------       30
      20000\ 190225296        6
       7000/ 189000000
             ---------
      34000\   1225296
         30/   1020900
               -------
      34060\    204396
          6/    204396
                ------
                     0
```

The following are the successive conclusions:—

$$290225296 - 10000^2 = 190225296$$
$$290225296 - 17000^2 = 1225296$$
$$290225296 - 17030^2 = 204396$$
$$290225296 - 17036^2 = 0$$

whence the given number is the square of 17036.

The rationale of the approximate extraction is as follows:—Suppose we wish to find, to four places of decimals, the square root of 1·74; that is, to find a fraction a, such that a^2 shall be less than 1·74, but that $(a+{\cdot}0001)^2$ shall be greater than 1·74. Give this fraction the denominator 1,00,00,00,00, which requires that its numerator shall be 1,74,00,00,00. This numerator is found, by the integer rule, to lie between 13190^2 and 13191^2, or 173976100 and 174002481. We have, then,—

$$(1{\cdot}3190)^2 = 1{\cdot}73976100$$
$$(1{\cdot}3191)^2 = 1{\cdot}74002481$$

which satisfy the conditions.

The common process of contraction, explained in books of arithmetic, has the following rule:—When the number of places in the divisor has so much increased as to exceed by 2 or more the number of places yet remaining to be found, instead of proceeding with the complete operation, leave the remainder unaugmented by any new period, strike one figure off the divisor, and proceed as in contracted division. If R be the remainder, a the part of the root found, b that remaining to be found, we have $b(2a+b)=\text{R}$. If a be very large compared with b, $2ab=\text{R}$ nearly, or $b=\text{R}\div 2a$ nearly; now $2a$ is the *divisor* in the rule. The fact is that b must lie between

$$\frac{\text{R}}{2a} \text{ and } \frac{\text{R}}{2a+\frac{\text{R}}{2a}}$$

Processes of this sort are often best shown, as to mere operation, by an instance in which the numerical computation gives no trouble. The following is a complete instance of the rule, exhibited in finding the square root of 4444·444444, &c.:—

```
            4̇44̇4̇·44̇44̇44̇, &c. (66·666666666667
            36
       126)844
            756
       1326)8844
             7956
       13326)88844
              79956
       133326)888844
               799956
       1333326)8888844
                7999956
       13333326)88888844
                 79999956
 13,3,3,3,3,3,2)8888888
                7999999
                 888889
                 800000
                  88889
                  80000
                   8889
                   8000
                    889
                    800
                     89
                     80
                      9
                      9
                      0
```

The given number is, in fact, 4444$\frac{4}{9}$, which is the square of 66$\frac{2}{3}$.

When R is the remainder, and a the part of the root found, the remaining part of the root is the continued fraction [FRACTIONS, CONTINUED.]

$$\frac{\text{R}}{2a+}\;\frac{\text{R}}{2a+}\;\frac{\text{R}}{2a+}\;\frac{\text{R}}{2a+}\;\&\text{c.}$$

But this is not a continued fraction of the most useful form, except when R=1. To reduce the remainder of a square root to a continued fraction in which all the numerators are units, proceed as follows (the process comes first and is followed by the explanation):—

To extract the square root of 21—

```
4 | 1  3  3  1  4  4 | 1
1 | 5  4  3  4  5  1 | 5
4 | 1  1  2  1  1  8 | 1
```

Let the number be N, the integer part of its root a, and write under one another in the first column, a, 1, a. Proceed to form the second, third, &c., columns, each from the preceding, in the following way:—If p, q, r, be in one column (found), and $p', q'\ r'$ in the next (to be found), then—

1. q' is $\dfrac{\text{N}-p^2}{q}$, and is always integer.
2. r' is the integer part of $\dfrac{a+p}{q'}$.
3. p' is $q'r'-p$.

Thus, for the second column we have $(21-16)\div 1$, or 5, for the second row; the integer of $(4+4)\div 5$, or 1, for the third row; and $1\times 5-4$, or 1, for the first row. In the third column we have $(21-1)\div 5$, or 4, for the second row; the integer of $(4+1)\div 4$, or 1, for the third row; and $1\times 4-1$, or 3, for the first row. In the fourth column we have $(21-9)\div 4$, or 3, for the second row; the integer of $(4+3)\div 3$, or 2, for the third row; and $2\times 3-3$, or 3, for the first row, and so on. This process must, after a time, begin to repeat itself; as soon as this happens, the last row shows the integer of the square root, and th succession of denominators of the continued fraction, which must be repeated as often as is necessary to give the required degree of accuracy. Thus,

$$\sqrt{21} = 4 + \frac{1}{1+}\;\frac{1}{1+}\;\frac{1}{2+}\;\frac{1}{1+}\;\frac{1}{1+}\;\frac{1}{8+}\;\frac{1}{1+}\;\frac{1}{1+}\;\frac{1}{2+}\;\frac{1}{1+}\;\frac{1}{1+},\ \&\text{c.}$$

If we proceed with the continued fraction as in the article cited, we have for the successive approximations to its value—

$$\frac{1}{1}\;\frac{1}{2}\;\frac{3}{5}\;\frac{4}{7}\;\frac{7}{12}\;\frac{60}{103}\;\frac{67}{115}\;\frac{127}{218}\;\frac{321}{551}\;\frac{448}{769}\;\frac{769}{1320},\ \&\text{c.}:$$

and $4\frac{769}{1320}$ only differs from $\sqrt{21}$ in the 8th decimal place. The use of this method is, not to extract the square root of any number which accidentally occurs, but to find convenient approximations, if possible, for square roots which frequently occur, and as to which it is therefore worth examination whether there may not be some common fraction which will serve the purpose as well as a decimal of considerable accuracy. For instance, we take $\sqrt{2}$ and $\sqrt{3}$, which represent the diagonals of a square and a cube having a unit for their sides. The processes are as follows:—

```
1 | 1  1, &c.        1 | 1  1  1  1, &c.
1 | 1  1, &c.        1 | 2  1  2  1, &c.
1 | 2  2, &c.        1 | 1  2  1  2, &c.
```

$$\sqrt{2} = 1 + \frac{1}{2+}\;\frac{1}{2+}\;\frac{1}{2+\&\text{c.}}\qquad \sqrt{3} = 1 + \frac{1}{1+}\;\frac{1}{2+}\;\frac{1}{1+}\;\frac{1}{2+},\ \&\text{c.}$$

The successive approximations to the fractions are—

$$\frac{1}{2}\;\frac{2}{5}\;\frac{5}{12}\;\frac{12}{29}\;\frac{29}{70}\;\frac{70}{169}\;\frac{169}{408}\;\frac{408}{985},\ \&\text{c.}$$

$$\frac{1}{1}\;\frac{2}{3}\;\frac{3}{4}\;\frac{8}{11}\;\frac{11}{15}\;\frac{30}{41}\;\frac{41}{56}\;\frac{112}{153}\;\frac{153}{209}\;\frac{418}{571}\;\frac{571}{780},\ \&\text{c.}$$

Thus we immediately see a convenient mode of finding the diagonal of a square, derived from

$$\sqrt{2} = 1 + \frac{29}{70} = \frac{99}{70} = \frac{100-1}{70},\ \text{nearly},$$

the excess of which above the truth is less than the 11830th part of the side. Thus, to find the diagonal of a square of 769·23 feet, we have

```
  76923
    769·23
  ----------
70)76153·77
    1087·911
```

which is too great by only about 6-hundredths of a foot.

The rule for extracting the square root of an algebraical quantity is very little needed, but is a remarkably good exercise in the operations of algebra. Arranging the square in powers of some one letter, the rule is identical with that for the square root of numbers in every point but this, that the new term is always found by dividing the *first term* of the remainder by the *first term* of the divisor. A couple of examples will suffice. Let it be required to find the square root of $1+2x+3x^2+4x^3+\ldots$.

$$\begin{array}{rl}
 & 1+2x+3x^2+4x^3+\ldots\ldots \qquad (1+x+x^2+x^3+\ldots \\
 & 1 \\ \hline
2+x) & 2x+3x^2+\ldots \\
 & 2x+x^2 \\ \hline
2+2x+x^2) & 2x^2+4x^3+5x^4+\ldots\ldots \\
 & 2x^2+2x^3+x^4 \\ \hline
2+2x+2x^2+x^3) & 2x^3+4x^4+6x^5+7x^6 \\
 & 2x^3+2x^4+2x^5+x^6 \\ \hline
 & 2x^4+4x^5+6x^6
\end{array}$$

Again, to find the square root of $1+x$:

$$\begin{array}{rl}
 & 1+x\left(1+\frac{x}{2}-\frac{x^2}{8}+\frac{x^3}{16}-\frac{5x^4}{128}+\ldots\right. \\
 & 1 \\ \hline
2+\frac{x}{2}) & x \\
 & x+\frac{x^2}{4} \\ \hline
2+x-\frac{x^2}{8}) & -\frac{x^2}{4} \\
 & -\frac{x^2}{4}-\frac{x^3}{8}+\frac{x^4}{64} \\ \hline
2+x-\frac{x^2}{4}+\frac{x^3}{16}) & \frac{x^3}{8}-\frac{x^4}{64} \\
 & \frac{x^3}{8}+\frac{x^4}{16}-\frac{x^5}{64}+\frac{x^6}{256} \\ \hline
 & -\frac{5x^4}{64}+\frac{x^5}{64}-\frac{x^6}{256}
\end{array}$$

SQUINTING (*Strabismus*). It is a condition essential to correct vision that the axes of both eyes correspond in direction, and be turned simultaneously towards the object we regard. Now to ensure the fulfilment of this condition, the orbital muscles (motores oculorum) are so supplied with nervous influence, that we cannot will the movement of one eye without the other being called into involuntary and harmonious action. There are some individuals, however, whose optic axes are not parallel, and whose eyes do not move in harmony with each other; such persons are said to squint, or to be affected with strabismus. Squinting may take place either upwards, downwards, inwards, or outwards, or in the intermediate directions; it may also be confined to one eye; or may affect both. As the inward and outward varieties of squint are by far the most common, we shall devote the following remarks to them alone.

Inward Squint, or Strabismus convergens, is met with in three distinct forms: 1, single convergent strabismus; 2, double convergent strabismus; and 3, alternating strabismus. In the first form of the affection one eye is habitually turned more or less inwards towards the inner angle of the orbit, whilst the other maintains its natural position, and is capable of being directed to any object that the individual wishes.

On closing the sound eye, the inverted one then becomes straight, and can be turned in every direction nearly to the same extent as the other; but as soon as it is again opened, the one affected with strabismus revolves inwards, and there remains; or if it do move along with the good eye, yet never so as to permit the two axes to be pointed at the same object. Double convergent strabismus differs from the preceding in its affecting both eyes; the axis of each eye is inclined unnaturally inwards, as if the person were regarding some object placed close to his face. On directing his attention to distant objects, the eyes do not become parallel, but the one least affected (for one is always more so than the other) becomes straight, whilst its fellow preserves its former position, or is turned more strongly inwards. With regard to the relative frequency of strabismus in one or in both eyes, it is said to affect most frequently one eye only, and this the left.

Alternating Strabismus differs from the ordinary form of squint, in its affecting both eyes *equally*, though never both at a time. An individual thus affected appears to use either eye indifferently; and the change of inversion from one eye to the other is a voluntary act, independent of the opening or closing of the eyelids.

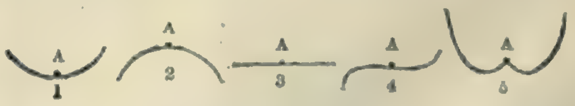
Outward Squint, or Strabismus divergens.—Nearly all that has been said in reference to convergent strabismus, may be applied, *mutatis mutandis*, to divergent squint. In this form of the affection, one eye is more or less everted, whilst the other is directed straight forwards; the patient is likewise incapable of directing both eyes inwards simultaneously. These cases we believe to be most frequently of the alternating kind; that is, the individual can employ either eye singly, and bring it into the central axis, but then its fellow becomes everted. It is a more rare affection than the former one, and the deformity arising from it is seldom so obvious. Whether we regard strabismus as affecting one eye or both, it is certain that the vision of the one most distorted is nearly always imperfect, and usually in a direct ratio with the degree of distortion. Now we know that if impressions on the two retinæ are dissimilar in force, the mind disregards the weaker, and takes cognizance only of the stronger; so that a person who squints badly generally sees objects with the sound eye only. If the sight of both eyes is equal or nearly so, double vision results whenever both are employed together, because the images of objects do not fall on corresponding portions of the two retinæ [SIGHT, DEFECTS OF]; and as the defect of sight is generally in a direct ratio with the degree of distortion, double vision is most frequently experienced in slight cases of squint.

Causes.—The inequality of power in the two eyes has been regarded by many as a cause of strabismus; the defective eye, it is said, "instead of being fixed on the object before it, is left to wander from the true axis of vision." When, however, we consider how numerous are the examples of unequal vision with the two eyes, yet unattended with squint, and the great and immediate improvement of sight which generally results from the operation for the removal of the defect, we may fairly question the influence of this cause in the production of strabismus. Among the remote causes which unquestionably contribute to this effect, may be enumerated convulsions, teething, the irritation arising from worms, ophthalmia, imitation, a habit of misdirecting the eyes, as by frequently looking at a mole on the nose, &c. The proximate cause resides in some affection of the muscles or nerves of the eyeball; either the balance of power between the former is lost, or the sympathy which exists naturally between the motor-oculi nerves of the two eyes is impaired.

Treatment.—This must depend upon whether the affection is of a temporary or permanent nature; in the former case it will be found to arise from some local irritation, and can be removed by suitable therapeutic remedies; in the latter, an operation will generally be required. Among the different other plans of treatment which occasionally have proved successful, we may enumerate binding up the sound eye; the employment of spectacles having glasses of different power; blinders projecting in front of the temples, with a view of attracting the eyes outwards; electricity, &c. The operation for the cure of strabismus is said to have suggested itself first to Dr. Stromeyer, from witnessing the success of tenotomy in contractions of the limbs. Dr. Dieffenbach of Berlin, however, was the first who had the boldness to carry it into practice on the living subject. The operation consists in dividing the muscle by which the distortion is produced, and thus allowing its antagonist to draw the eye again into the centre of the orbit. Although most cases of strabismus may be either completely cured or very much bettered by this operation, it is proper to remark that in some, neither this nor any other plan of treatment is of any avail. Provided, however, that the subjects to be operated on are judiciously selected, and the surgeon qualified for the task, there is no operation within the whole range of surgery which is more simple, more free from danger, or more satisfactory in its results, than the one in question.

STABLE AND UNSTABLE; STABILITY. A system is said to be stable when a slight disturbance of its actual condition would not produce a continually increasing effect, but one which finally ceases to increase, diminishes, becomes an effect of a contrary character, and so on, in an oscillatory manner. The ordinary vibration of a pendulum is an instance; the oscillation takes place about a stable position of equilibrium. We can give no instance of an unstable position; for by definition, such a thing is a mathematical fiction. Any disturbance, however slight, produces upon an unstable system an effect which continually increases: no unstable equilibrium therefore can exist a moment, for no system made by human hands can be placed with mathematical exactness in a given position. The pendulum has a position of equilibrium exactly opposite to that about which it can oscillate, but no nicety of adjustment will retain it in that position: it may appear to rest for a moment, but will almost instantly begin to fall.

The following curves or lines are all such that, supposing them to be rigid matter, a molecule placed at A would rest:—



In the first, a displacement to the right or left would produce nothing but oscillation, and the equilibrum is stable; in the second, neither displacement would be followed by any tendency to restoration, and the equilibrium is unstable; in the third, displacement would only be a removal to another position of rest, and the equilibrium is called indifferent. In the fourth, displacement to the right would be followed by restoration, but the velocity acquired in restoration would carry the molecule to the left, on which side there is no tendency to restoration: the equilibrium would then be permanently disturbed, and practically unstable; though it might be convenient to say that it is stable as to the disturbances to the right, and unstable as to those to the left. In the fifth, the equilibrium at A is unstable, but if a push, however slight, were given to the molecule, it would obviously, by reason of the two contiguous stable positions, oscillate about A, as if A were itself a stable position: and in the same manner a stable position, with an unstable one near to it, might, for a disturbance of sufficient magnitude, present the phenomena of an unstable position.

Now, suppose that the point A, instead of being a single molecule, is the centre of gravity of a system acted on by its own weight only; and let the curve drawn be the path of the centre of gravity, which, owing to the connection of the parts of the system with its supports, that centre is obliged to take. The phenomena of the single point still remain true: there is in every case a position of equilibrium when the system is placed in such a position that its centre of gravity is at A. In (1) the equilibrum is stable; in (2), unstable; in (3), indifferent; in (4), stable or unstable, according to the direction of disturbance; in (5), unstable, with results like those of stability. It is an error to state, as is frequently done, that there is no equilibrium in such a system except when its centre of gravity is highest or lowest; as is obvious from (3) and (4). The general proposition which *is* true is this—that a system acted on by its own weight is in equilibrium then, and then only, when its centre of gravity is placed at that point of its path which has its tangent parallel to the horizon, or perpendicular to the direction of gravity.

When a system is supported on three or more points, it is well known that there is no equilibrium unless the vertical passing through the centre of gravity cuts the polygon formed by joining these points. This must not be confounded, as is sometimes done, with a case of distinction between stable and unstable equilibrium; for it is a case of equilibrium or no equilibrium, according as the central vertical cuts or does not cut the base of the figure. Of course it is in the power of any one to say that stability means equilibration and instability non-equilibration; but such is not the technical use of these words in mechanics: stability and instability refer to equilibrium, stable equilibrium being that which would only be converted into oscillation by a disturbance, and unstable equilibrium that which would not be so converted.

Neither must the effects of friction or other resistances be confounded with those of a stable or unstable disposition. A ladder resting against horizontal ground and a vertical wall is maintained by friction; were it not for friction, there would not be rest in any position; and as it is, the angle which the ladder makes with the ground must not be too small. There is thus a set of positions, from the vertical one to a certain inclination, depending on the amount of friction, in all of which there is equilibrium; while in every other position there is no equilibrium. In no case must the words stability and instability be used in such manner as to confuse their popular with their technical sense.

Under Solar System is pointed out what is meant by the stability of that system. When a system has a motion of a permanent character, it is stable if a small disturbance only produce oscillations in that motion, or make permanent alterations of too slight a character to allow the subsequent mutual actions of the parts to destroy the permanent character of the motion. Suppose a material body, for instance, to revolve about an axis passing through the centre of gravity unacted on by any forces except the weight of its parts. If this axis be one of the principal axes, the rotation on it is permanent, that is, the axis of rotation will continue unaltered, even though that axis be not fixed. The rotation however, though permanent, is not *stable* about more than two out of the three principal axes. Let the first rotation be established about the axis which has the greatest moment of rotation, or the least, and if a slight displacement or disturbance be given, which has the effect of producing a little alteration of the axis of rotation, that alteration will not increase indefinitely, but will only occasion a perpetual transmission of the rotation from axis to axis, all the lines lying near to the principal axis first mentioned. But if that axis be chosen about which the moment of inertia is neither greatest nor least, any disturbance, however slight, will continually remove the axis of rotation farther and farther from the first axis, near which it will not return until it has made a circuit about one of the other two principal axes.

For the mathematical part of this subject, so far as we give it, see Virtual Velocities.

STADE DUTIES are so called from Stade, in the kingdom of Hanover, a town situated on the right bank of the Schwinge, three or four miles from where it falls into the Elbe, and 22 miles west by north from the city of Hamburg. The name *Brunshausen Tolls* is now more commonly used, from the village of Brunshausen, at the mouth of the Schwinge, where there is a custom-house and a royal guard-ship, and where the duties are collected which are levied on vessels and merchandise passing up the Elbe. The original duties, which were regulated by a treaty made in 1691, were light, but were gradually increased by the Hanoverian government till they amounted to about 40,000*l.* a-year. The duties levied were about ⅛ per cent. *ad valorem*, more on some articles and less on others. British vessels by a proclamation of Geo. II., December 1, 1736, were allowed under certain regulations to sail directly up to Hamburg, without coming to anchor at the mouth of the Schwinge, as other foreign vessels were obliged to do.

By a convention between the King of Hanover and the heads of the other Elbe-bordering states (Emperor of Austria, King of Prussia, King of Saxony, King of Denmark, Duke of Mecklenburg-Schwerin, Duke of Anhalt-Coethen, Duke of Anhalt-Dessau, Duke of Anhalt-Bernburg, Free and Hanseatic town of Lübeck, and Free and Hanseatic town of Hamburg), dated April 13, 1844, in conformity with articles 108 and 116 of Act of Congress of Vienna, of June 9, 1815, the Brunshausen Tolls were revised, regulated, and settled according to a Toll-Tariff agreed upon by the contracting parties.

These rates, by a treaty with Great Britain in July, 1844, were to continue in force till January 1, 1854. The treaty was then renewed, temporarily, while the question of the abolition of the duties was considered, as they were felt to be oppressive and unjust, nothing being done to benefit the navigation in return for them. At length a compensation of 3,000,000*l.* was offered, of which Hamburg, which would derive the greatest benefit, was to pay one-third; Great Britain 1,125,206*l.*, and all the other commercial states of Europe with the United States of America the remainder, in proportion to their commerce. This has been agreed to, but the ratification has not yet been completed.

STA'DIUM (*ὁ στάδιος* and *τὸ στάδιον*), the principal Greek measure of length, was equal to 600 Greek or 625 Roman feet, that is, to 606 feet 9 inches English. The Roman mile contained 8 stadia. The Roman writers often measure by stadia, chiefly in geographical and astronomical measurements. (Herod., ii. 149; Plin., 'Hist. Nat.,' ii., 23 or 21; Columell., 'Re. Rust.,' v. 1; Strabo, vii., p. 497.)

The standard length of this measure was the distance between the pillars at the two ends of the foot-race course at Olympia, which was itself called *stadium*, from its length, and this standard prevailed throughout Greece. Some writers have attempted to show that there were other stadia in use in Greece besides the Olympic. The only passages in which anything of the kind seems to be stated are one in Censorinus ('De Die Natali,' c. 13), which, as far as it can be understood, evidently contains some mistake; and another which is quoted by Aulus Gellius (i. 1) from Plutarch, but which speaks of the race-courses called stadia, not of the stadium as a measure.

The principal argument for a variety of stadia is that of Major Rennell ('Geog. of Herod.,' s. 2); namely, that when ancient authors have stated the distances between known places, and a comparison is made between their statements and the actual distances, the distances stated by them are invariably found to be too great, never too small. Hence the conclusion is drawn that they used an itinerary stade shorter than the Olympic. If so, it is strange that the very writers who have left us these statements of distances have not said a word about the itinerary stade which they are supposed to have used, while several of them often speak of the Olympic stade as containing 600 Greek feet. But there is a very simple explanation of the difficulty, which is given by Ukert, in his 'Geographie der Griechen und Römer' (i., ii., p. 56, &c.). The common Greek method of reckoning distances, both by sea and land, was by computation, not by measurement. A journey or voyage took a certain number of days, and this number was reduced to stadia, by allowing a certain number of stadia to each day's journey. The number of stadia so allowed was computed on the supposition that circumstances were favourable to the traveller's progress; and therefore every impediment, such as wind, tide, currents, windings of the coast, a heavily laden or badly sailing ship, or any deviation from the shortest track by sea, and the corresponding hindrances by land, would all tend to increase the number of days which the journey took, and consequently the number of stadia which the distance was computed to contain. These circumstances, together with the fact that the Greek writers are by no means agreed as to the number of stadia contained in a day's journey, and other sources of inaccuracy which we know to have existed, furnish a satisfactory explanation of the discrepancies which we find in their statements of distances, both when compared with one another, and when compared with the actual fact, without there being any occasion to resort to the supposition of a stade different from the Olympic. Colonel Leake 'On the Stade as a Linear Measure' ('Journal of the Royal Geographical Society of London,' vol. ix., 1839), has also come to the conclusion "that the stade, as a linear measure, had but one standard, namely, the length of the foot-race, or interval between the *ἀφετήρια* and *καμπτῆρ* in all the stadia of Greece, and which is very clearly defined as having contained 600 Greek feet."

When we come however to writers as late as the 3rd century of the Christian era, we do find stadia of different lengths. Of these the chief are those of 7 and 7½ to the Roman mile. (Wurm, 'De Pond.,' &c., § 58.)

The following table, from the Appendix to Hussey's 'Ancient

Weights and Money,' represents the supposed varieties of the Greek stadium :—

	Yds.	Ft.	Inch.
Stade assigned to Aristotle's measurement of the earth's surface	109	1	2·26992
Mean geographical stade, computed by Major Rennell	108	1	6
Olympic stade	202	0	9
Stade of 7½ to the Roman mile	215	2	2·4
Stade of 7 to the Roman mile	231	0	5·124

2. The race-course for foot-races at Olympia was called stadium, as above mentioned, and the same name was applied to all other such courses.

The stadium consisted of a flat area, surrounded by raised seats, and was made either in a spot which had by nature the required shape, or in the side of a hill, or on a plain. In the last two cases the stadium was constructed by forming a mound of earth of the proper shape, and covering it with stone or marble for the seats. The second of these three forms was the most common. Of the third we have a fine example in the Panathenaic Stadium at Athens. The area of the stadium was oblong, terminating at one end in a semicircle. At the other end it was bounded by a wall, at the two extremities of which were the entrances, one on each side of the stadium. Here was the starting-place (*ἄφεσις*, *γραμμή*, *ὕσπληξ*, or *βαλβίς*), marked by a square pillar in the middle of the breadth of the area. Another such pillar was placed at the other end of the course, at the distance of a stadium from the former, and at or near the centre of the semicircular end of the area. This pillar marked the termination of the simple foot-race [OLYMPIAN GAMES], but in the Diaulus the runners turned round it and went back to the starting-place; in the Dolichus they turned round both pillars several times, according to the number of stadia of which the course consisted. The end of the course was called *τέρμα*, *βατήρ*, *τέλος*, *καμπτήρ* and *νύσσα*. Halfway between these pillars stood a third. On the pillar at the starting-place was inscribed the word *ἀρίστευε* (*excel*); on the middle one, *σπεῦδε* (*hasten*); on the one at the goal, *κάμψον* (*turn*). The semicircular end of the area (*σφενδόνη*) was thus not used in the foot-race. Here probably the other gymnastic contests took place; for though the stadium was originally intended only for the foot-race, yet as the other contests came to be added to the games, they also took place in the stadium, except the horse-races, for which a separate course was set apart, shaped like the stadium, but larger: this was called *ἱππόδρομος*.

Among the seats which surrounded the area, a conspicuous place, opposite to the goal, was set apart for the three Hellanodicae, who decided the contests, and who entered the stadium by a secret passage. Opposite to them on the other side of the stadium, was an altar, on which the priestesses of Demeter Chamyne sat to view the games. The area was ornamented with several altars and statues.

The position of the stadium was sometimes, but not always, in connection with the gymnasium.

Under the Romans many of the Grecian stadia were modified so as to resemble the amphitheatre.

There still exist considerable ruins of stadia: among the most remarkable of which are those at Delphi, Athens, Messene, Ephesus, and Laodicea.

(Pausanias, ii. 27, 6; vi. 20, 5, 6; ix. 23, 1; Müller's *Archäologie der Kunst*, sec. 290; Krause, *Die Gymnastik und Agonistik der Hellenen*, i., p. 131, &c.)

STADTHOLDER (*Statthalter* in German, *Stadhouder* in Dutch) means lieutenant or governor. The appellative Statthalter is used in the cantons of German Switzerland, to denote the civil officer who is next to the landamman or chief magistrate. In the federal republic of the Seven United Provinces of the Netherlands, the stadhouder was himself the first magistrate or president of the Union. When several of the towns of Holland revolted against the tyranny of the Duke of Alba, the lieutenant of King Philip of Spain, they chose for their governor William, prince of Orange, swearing allegiance to him as the king's stadhouder, thus implying that they had revolted against the Duke of Alba and not against King Philip. But it was not until after the death of William, in 1584, that the three united provinces of Holland, Zealand, and Utrecht agreed to have one stadhouder in common, and appointed to that office Maurice of Nassau, son of the deceased William. (Puffendorf.) From that time the stadhoudership continued in the house of Nassau till the death of William III. in 1702, when the male line of William I. becoming extinct, the office remained vacant, and was considered as tacitly abolished. But in 1747, after a struggle between the republican and the Orange parties, the latter, having triumphed, proclaimed William IV., of a collateral branch of the Nassau family, hereditary stadhouder of the Seven United Provinces. His son William V. was expelled by the French in 1795, and resigned the stadhoudership by treaty with France in 1802, since which the office has not been revived, the republic of the Netherlands having been transformed into a kingdom.

STAFF, in Music. The five parallel lines and the four spaces between the lines, on which notes and other musical characters are placed, are, collectively, called the *Staff*.

STAFF, MILITARY. In the British empire this consists, under the sovereign and the general commanding-in-chief, of those general, field, and regimental officers to whom is confided the care of providing the means of rendering the military force of the nation efficient, of maintaining discipline in the army, and regulating the duties in every branch of the service.

Besides the commander-in-chief, his military secretaries and aides-de-camp, the general staff consists of the adjutant and quartermaster-generals, with their respective deputies, assistants, and deputy-assistants, a deputy, assistant, and deputy assistant adjutant-general for the royal artillery, and a deputy and assistant adjutant general for the royal engineers; the director-general of the medical department, and the chaplain-general of the forces. The staff of the ordnance department consisted formerly of the master-general and lieutenant general, with their deputies and assistants: the inspector-general of fortifications, and the director-general of artillery, &c. The duties connected with the Ordnance having been transferred to the War Department, the office of master-general has been abolished, and the staff made a part of the War Office. The head-quarters for the general staff are in London. There are also, for the several military districts into which Great Britain is divided, inspecting field-officers, assistant adjutants-general, and majors of brigade, together with the officers attached to the recruiting service. The head-quarters for Scotland are at Edinburgh. For Ireland, besides the lord-lieutenant and his aides-de-camp, the chiefs of the staff consist of a deputy-adjutant and a deputy-quartermaster-general, with their assistants. Their head-quarters are at Dublin; and there are, besides, the several officers for the military districts of that part of the empire. Lastly, in each of the colonies there is a staff graduated in accordance with the general staff of the army, and consisting of the general commanding, his aides-de-camp, military secretaries, and majors of brigade, an inspecting field-officer, a deputy-adjutant, and a deputy-quartermaster-general.

The adjutant-general of the army is charged with the duty of recruiting, clothing, and arming the troops, superintending their discipline, granting leave of absence, and discharging the men when the period of their service is expired. To the quartermaster-general is confided the duty of regulating the marches of the troops, providing the supplies of provisions, and assigning the quarters, or places of encampment.

All military commanders of territories or of bodies of troops in Great Britain, Ireland, or in foreign stations, transmit periodically to the adjutant-general of the army circumstantial accounts of the state of the territory and of the troops which they command; and the reports are regularly submitted to the general commanding-in-chief.

The staff of a regiment consists of the adjutant, quartermaster, paymaster, chaplain, and surgeon.

The first establishment of a permanent military staff (état majeur, as it was called) was made in France in 1783, about the conclusion of the Revolutionary war between Great Britain and the United States of America. The officers who held the highest rank in it were considered as assistant-quartermaster-generals, and their deputies as captains. The first duties consisted in collecting the reports, the orders, and instructions which had formerly passed between the generals of the French armies and the minister of war, together with the plans of the ground on which the most important actions had taken place; and from these documents it was endeavoured to acquire a knowledge of the causes of success or defeat as far as these depended on the dispositions of the troops and the nature of the ground. The persons who were allowed to enter the department of the état majeur were such as, to a knowledge of the general theory of military tactics, added that of topographical surveying, and who were skilful in the art of representing on a plan the features of ground so as to present to the eye at once a view of its capabilities as a military position, and of the facilities which it might afford for the march of troops with their artillery and stores.

About the year 1800 the British government first formed a particular school for the purpose of instructing officers in the art of surveying ground in connection with that part of tactics which relates to the choice of routes and of advantageous positions for troops. These officers were independent of the master-general of the ordnance, and served under the orders of the quartermaster-general or adjutant-general; they were called staff-officers, and were selected from the cavalry or infantry after having done duty with a regiment at least four years. They were first employed in Egypt, where they rendered considerable service; and the school was afterwards united to the Royal Military College, which had been then recently instituted for the instruction of cadets who were to serve in the cavalry or the infantry of the line. At that institution a limited number of officers, under the name of the senior department, continue to be instructed in the duties of the staff, and in the sciences connected with the military art. All officers are now obliged to pass an examination before they can be employed on the staff of the army, and they may either enter the Staff College at Sandhurst by a competitive examination, and remain there for two years, or may qualify for the staff by passing the same examination as is required of the officers at Sandhurst at the end of their course of study.

During the war in Spain, from 1808 to 1813, the staff-officers were constantly employed, previously to a march or a retreat, in surveying the country at least one day's journey in front of the army. After the death of the Duke of York, the staff corps ceased to be kept up, and for several years it was reduced to a single company, which was charged with the duty of repairing the military canal at Hythe. This company was afterwards incorporated with the corps of sappers and miners.

The duties of officers belonging to the quartermaster-general's staff, though in certain respects similar, are different from those of the military engineers; the latter are employed in the construction of permanent fortifications, batteries, and field-works; while the former survey ground in order to discover roads, or sites for military positions, for fields of battle, or quarters for the troops. The education of a staff-officer is such as may qualify him for appreciating the military character of ground: for this purpose he learns to trace the directions of roads and the courses of rivers or streams; and in mountainous countries to distinguish the principal chains from their ramifications, to examine the entrances of gorges, and to determine the heights of eminences or the depths of ravines. He has, besides, to acquire a facility in determining or estimating the resources of a district with respect to the means it affords of supplying provisions or quarters for the troops. [RECONNAISSANCE.]

The staff-officer ought also to know how to correct the illusions to which the eye is subject in examining ground, from the different states of the air, and the number and nature of the objects which may intervene between himself and those whose positions are required. He ought to be able to estimate the number of men whom a visible tract of ground can contain, and to form a judgment concerning the dispositions and stratagems which it may permit an army to put in practice.

STAGE CARRIAGE. Although the law regards differently a *stage* carriage and a *hackney* carriage, we may conveniently treat of both here. The former group comprises *stage coaches* and *omnibuses*, for the use of which passengers pay at the rate of so much per journey; the latter group comprises *hackney couches* and *cabs*, for which passengers pay either at so much per mile or so much per quarter of an hour. As to coaches generally, it needs simply to be observed here, that they were introduced into England about 1570, and that a long time elapsed before their use became customary among wealthy persons.

Hackney Carriages.—The derivation of the word Hackney, as applied to a class of public conveyances, has occasioned much speculation. The suburb of *Hackney;* the French *Hacquenée* and *Haque*, both derived from the Latin, *equus*, a horse; and the Anglo-Saxon equivalent for "neighing" have been severally proposed as the probable origin for the name. However this may be, it is sufficiently evident that the term *hackney* was first applied to horses let for hire, and then, by a very natural transition, extended to coaches, and subsequently to sedan-chairs, employed in a similar way.

Hackney carriages appear to have originated in London. It was in 1625 that they began to ply in London streets, or rather at the inns, to be called for as they were wanted; and they were at this time only twenty in number. In 1634 sedan-chairs appear, for the first time, to have entered into competition with hackney-coaches, the sole privilege being granted in that year to Sir Sanders Duncomb. In the following year an attempt was made to check the increasing annoyance occasioned by the "general and promiscuous use of coaches" by a proclamation from the king (Charles I.) that no hackney or hired coach should be used in London, Westminster, or the suburbs, unless it were engaged to travel at least three miles out of the same; and that every hackney-coach owner should constantly maintain four able horses for the royal service when required. Finding it impossible to prevent the use of so great a convenience, a commission was issued to the master of the horse in 1637 to grant licences to fifty hackney-coachmen in and about London and Westminster, and as many others as might be needful in other places in England, each coachman being allowed to keep not more than twelve horses. In 1652 the number of hackney-coaches daily plying in the streets was limited to 200; in 1654 it was increased to 300, allowing however only 600 horses; and an increase was at different times allowed till 1771, when the number of coaches was further increased to 1000. Notwithstanding this steady increase in the use of hackney-coaches, they were long assailed as public nuisances.

The first hackney-coach *stand* was established in 1634, by one Captain Baily, near the May-pole in the Strand. Even so late as 1660 Charles II. issued a proclamation against hackney-coaches standing in the streets to be hired. The monopoly long enjoyed by the London hackney-coachmen produced great indifference to the increasing wants of the community; even down to the year 1823, while that monopoly was undisturbed, hackney-coaches appear to have sunk lower and lower in the scale of efficiency.

While this was the state of things in London, a lighter kind of vehicle, drawn by one horse, called *cabriolets de place*, had been brought into extensive use in Paris. But it was not till 1823, and then with great difficulty, that licences were obtained for eight cabriolets to be started at fares one-third lower than those of hackney-coaches. The new vehicle was a hooded chaise, drawn by one horse, and carrying only one passenger besides the driver, who sat in the cabriolet (or, as more commonly called for brevity, the *cab*), with his fare. An improved build was soon introduced, by which room was provided for a second passenger, and the driver was separated from the fare. With the rapid extension of this lighter class of vehicles, numerous varieties of construction have been introduced, in which comfortable and safe accommodation, with complete shelter from the weather and separation from the driver, is provided for two, three, or four persons. The name *cab* is still commonly applied to all hackney-carriages drawn by one horse, whether on two or four wheels. During the first few years of the employment of such carriages their number was restricted to 65, while the number of coach-licences was increased to 1200; but in 1832 all restriction as to the number of hackney carriages was removed.

Since the year 1822 hackney carriage-drivers have been required to deposit any articles which may be accidentally left in their vehicles with the registrar of licences, to whom the owners of the lost property may apply for its restoration. The property thus recovered has often exceeded 10,000*l.* in a single year. To lessen the risk in reference to one important department of hackney carriage business, the railway companies which have termini in London enter into arrangements by which a limited number of carriages, driven only by men of well attested respectability, are allowed to stand within their stations, to convey passengers to their respective destinations, under a system of supervision so strict, that any case of misconduct or overcharge is almost certain to be brought home to the guilty party.

The hackney carriages of the metropolis are now regulated as to vehicles, drivers, and fares by the Act 16 & 17 Vict. c. 33, (1853). Every owner of a stage-carriage must be licensed. On applying to the Commissioners of Police for a licence, his vehicle is to be inspected; if it be approved on inspection, the Commissioners grant a certificate, stating how many persons the vehicle is permitted to carry. On the presentation of this certificate, the Board of Inland Revenue grants a licence. The police commissioners are empowered, at any time deemed by them proper, to order an inspection of metropolitan stage and hackney-carriages and horses; if any are found in improper condition, notice thereof is sent to the proprietor; if he neglect to attend to this warning, the commissioners may suspend his licence for a stated time, and take away his Stamp Office plate until after the expiration of that time. The fares for hackney-carriages are fixed at 6*d.* for every mile or fraction of a mile, or 2*s.* per hour. Back fares are disallowed; but 6*d.* per quarter of an hour is allowed for detention. Each hackney-carriage is to be provided with a table of fares, and each driver with a book of fares, which he is to produce when required. The driver must not refuse to carry a fare, if the distance be within six miles or the time within an hour; beyond these limits he may exercise an option. When hired by time, the driver is not bound to go more than four miles an hour, unless paid 6*d.* per mile extra. The driver is to give a ticket to his fare, inscribed with the Stamp Office number of the carriage. The carriage must contain, in writing, a notification of the number of persons it may carry at once. A reasonable quantity of luggage is to be taken free of charge. Property left in carriages is to be accounted for, by the driver, under certain regulations. Lamps are to be lighted in or on the carriages at night. The police are to have control over all the coach-stands. In the cases where a hackney-carriage is drawn by more than one horse, an addition of one-third may be made to the fare. The driver may refuse to charge by time instead of distance, between eight in the evening and six in the morning. If more than two persons ride in a hackney carriage, 6*d.* for each is charged (over any distance) beyond the regular fare.—All these provisions are enforced by fine or imprisonment.

The above act related chiefly to hackney-carriages in connection with the public. Another, relating to their connection with the revenue, was passed in the same year (16 & 17 Vict. c. 127). The old duties (5*l.* for a licence, and 10*s.* per week) were repealed, and lower duties imposed. The licence for every hackney-carriage is to be 2*l.*, and the duty is to be 6*s.* or 7*s.*, according as the carriage is to be worked six or seven days in a week. Every licence is for one year only, and is to be renewed annually. The number-plate is proof of the licence. Drivers are entitled to charge 1*s.* per mile instead of 6*d.* for any portion of their route beyond four miles from Charing Cross; provided the carriage is *discharged* beyond that limit. A proprietor must not withdraw his hackney-carriage from plying, beyond one day at a time, without giving notice of his intention to that effect.

We must here state that hackney carriages, as regulated by law, comprise only those which work within the police limits of the metropolis. Beyond those limits, the owners have to pay *post-horse duty* [POSTING], and possibly some local tax imposed by municipal authorities; but none of the duties mentioned in this article. The sum contributed to the national revenue by the London cabs (for in the middle of 1860 there was only *one* pair-horse hackney-coach left) is considerable. The duty of a shilling a day brings in about 80,000*l.* or 85,000*l.* per annum; while the cab licence, and the drivers' and watermen's licences, raise this to about 4000*l.* more. There were rather over 5100 London cabs in the middle of 1860. The drivers are more numerous than the cabs; for there are often a day driver and a night driver for the same vehicle. The six-day cabs, which do not run on Sundays, bear for distinction numbers expressed by five figures, beginning with 10,000. Of the sum realised by the government from the metropolitan cabs, about 13,000*l.* is annually handed over to the Commissioners of Police, to defray the expenses of supervision, watermen, coach-stands, &c. It is computed that seven horses are on an average kept for three cabs. Some of the cab-masters own above fifty vehicles each; most of them own a few only: and in certain cases the cabman is the owner of the vehicle which he drives. The patent or 'Hansom' cabs, peculiar for their construction and their high speed, are well-horsed; and there is observable a gradual improvement in the general condition of the horses employed in the London cabs.

In Paris, the hackney carriages are under strict regulation. The general custom has been to charge so much for a *course*, or journey, whether long or short, provided it be within the limits of Paris. This charge used to be one franc; but practically, a fee to the driver raised it to a few sous more. A few years ago this system was changed; every vehicle was provided by the authorities with a timepiece or watch, and fares were charged by the hour. For some reason this system was abandoned after a trial, and the old method of paying for the course resumed. The pernicious custom of allowing the driver to demand a fee or "pour boire," without defining its amount, continues.

Stage Carriages.—We have next to notice those public carriages which run regular stages or routes, and which charge by the journey, not by the mile or the hour.

Stage-coaches were first used in England soon after the introduction of hired carriages. In Scotland, in 1678, Provost Campbell established a coach to run from Glasgow to Edinburgh, "drawn by sax able horses, to leave Edinboro' ilk Monday morning, and return again (God willing) ilk Saturday night." The first mail coach travelled from London to Edinburgh about 1785, and to Glasgow in 1788. Springs were the first means towards better travelling; since their invention, the increased speed and better appointment of English stage-coaches have been caused by the improvement of roads, in conjunction with the great demand for rapid travelling. In this country the best stage-coaches were very perfect machines, and the arrangements by which they were conducted were well-planned, but some deterioration has taken place since their very general displacement by railways. The expense of *horsing* a four-horse coach, running at the speed of from nine to ten miles an hour was reckoned at 3*l.* a double mile for 28 days (a lunar month); so that a person horsing ten miles of a coach passing backwards and forwards each day, required to earn or receive by way of remuneration 13 times 30*l.* or 390*l.* a year for his work. Mails are exempt from turnpike tolls, but a tax is paid for them to the government, and mileage to the contractor for the use of the coach. The Post-office allows them a certain sum, determined by circumstances, per mile for carrying the letters; in consideration of this, it claims a right to limit their number of passengers, and regulate their speed and time of starting: the guard is the servant of the Post-office.

Short-stage-coaches, plying in the neighbourhood of towns, have been nearly superseded by omnibuses.

Until about the year 1830, in the metropolis a few slow and unpunctual stages were the only means of transit provided for the citizens to convey them to their suburban residences. A little earlier, only one stage plied from Paddington to the Bank; and this single vehicle, going in the morning and returning at night, was not always full. Its fares were two shillings inside, and eighteen-pence outside. The old stage-coaches could only carry four, or at most six, inside passengers; and when an attempt was made, about the year 1800, to introduce a more commodious kind of vehicle, resembling an omnibus, the project failed, in consequence of a general prejudice against the hearse-like appearance of the carriage. The long-bodied carriage then tried was drawn by four horses, and had six wheels. When re-introduced from Paris, the omnibus had four wheels, but was much longer and heavier than at present, and was drawn by three horses abreast. The first successful omnibus in London was started by a coach-builder named Shillibeer, in 1829, to run between Greenwich and Charing-Cross, at fares considerably less than those of the old short stages; in addition to which advantage, the greater part of the passengers were sheltered from the weather. Success in the first experiment led Shillibeer to establish omnibuses between Paddington and the Bank. After opposing the innovation most violently for a time, the old coach-proprietors followed his example, started omnibuses of their own, and by combined opposition succeeded in driving him entirely off the road; not, however, before the new system of travelling was fully established.

A few notices concerning the omnibus system of the present day may be added; but we must first speak of the legislation on the subject of stage-carriages.

In 1799 the Act of Parliament was passed (19 Geo. III., c. 51) which first imposed a duty on hired carriages of any description. This duty has at times been variously regulated. By an Act passed in 1833, the duty on stage-coaches was made to depend on the number of miles such carriage is authorised by the licence to travel in the day, week, or month, as the case may be. This duty might be compounded for. Every stage-carriage is to have a numbered plate affixed to it; a licence is necessary for every pair of plates, and the number of passengers each carriage is allowed to carry is stated in the licence. These regulations are applicable to all such carriages throughout the country, and include the more recently introduced *omnibus*, a word in no way recognised by the legislature. The conduct of the stage-carriages which are employed in London and within ten miles of the General Post-office, is further regulated by an Act passed in 1838, in which they are directed to be called "metropolitan stage-carriages," and by which, besides the rules applicable by previous acts to these conveyances as stage-carriages, other enactments are made as to the Stamp-Office plates, &c. It also empowers the Secretary of State to appoint a Registrar of Metropolitan Stage-Carriages, whose duty it is to issue the licence which the Commissioners of Stamps are authorised to grant to drivers and conductors. These licences the registrar may grant to any person above 16 years of age who can produce certificates of his ability to drive, and of good character. The licence is renewable yearly, and with it is given an abstract of the laws and penalties to which the receiver is amenable, and a numbered ticket, the latter of which he is to wear conspicuously on his person, and not to transfer or lend. The duty is calculated in the proportion of so much per mile according to the number of passengers the carriage may be licensed to carry.

Another regulative Act was passed in 1843. Proprietors are, as before, to fix their own fares; but the list of fares is to be painted within-side the coach or omnibus. A further Act, passed in 1855, contained two or three clauses relating to stage-carriages. The mileage duty is reduced from 1½*d.* to 1*d.* per mile. The charge for a supplementary licence is reduced from 5*s.* to 1*s.* On the other hand, the liberty to compound for stage-carriage duties is withdrawn.

In 1836, a joint-stock association called the "London Conveyance Company" was established, which proposed to run omnibuses along the principal lines of traffic, starting at short and regular intervals, and conducted by men of sober and respectable character. The result of this experiment was so successful, that other owners formed themselves into bodies of similar character. In the course of a few years the association system was almost universally adopted in the metropolis. For some years the traffic from Paddington to the Bank through Holborn was managed by the London Conveyance Company, with more than eighty omnibuses, and not less than a thousand horses. Each of the omnibuses performed upon an average six double journeys per day, and required at least ten horses to work it, independent of casualties. These horses were selected for strength and activity, and an experienced veterinary surgeon, with a staff of assistants and farriers, was employed to attend to them. The annual receipts of this company alone were roughly estimated at 80,000*l.* to 100,000*l.* About the year 1844 it was found that, out of 1400 metropolitan omnibuses, 200 were engaged on various routes to Paddington. In 1855 a "London General Omnibus Company" was established. It was of French origin, as a *Société en Commandite*, but was afterwards transformed into an English Company with limited liability. A capital was raised by shares; and the company proceeded, not to establish new omnibuses and omnibus routes, but to purchase those already existing. The sets of omnibuses known as the "Wellington," "Atlas," "Waterloo," "Favourite," &c., were one by one bought up. On an average the company purchased eleven horses with each omnibus. In order to propitiate the public the company promised new and superior vehicles. They offered a prize of 100*l.* for a design for an improved omnibus; but though the prize was awarded, the company have not adopted that or any other particular model in the build of their omnibuses. The operations gradually extended until the company became possessed of more than 600 omnibuses: each omnibus, with its stud of horses, harness, and "goodwill" of the business already established, cost on an average about 700*l.* The horses exceed 6000 in number. It has been found that these metropolitan omnibuses, one with another, run more than 20,000 miles a year each. In renewing the stock the average expenditure has been about 120*l.* per omnibus, 30*l.* per horse, and 12*l.* harness. Each horse, under average prices, costs 26*s.* per week for food, litter, medicine, shoeing, attendance, &c. The "wear and tear" of omnibus and harness per week is about 24*s.* The horses run about 12 miles per day each on an average.

The transactions of this company during the year 1860 present a strange result in a financial point of view: 40,000,000 passengers had been conveyed, and had paid about 589,000*l.* to the company for that service; but the expense incurred in rendering the service was 591,000*l.*, showing a small but actual loss on the whole year's operations, and leaving no dividend whatever for the invested capital. The receipts show an average of about 3½*d.* per passenger.

The omnibuses in Glasgow, Liverpool, Manchester, and several other towns, are in most respects superior to those of London. Projects have been formed for running omnibuses on tramways in the public streets; this plan was commenced at Birkenhead in 1860.

The mileage duty paid to the government for the metropolitan omnibuses amounts to about 70,000*l.* a year; to which is added about 15,000*l.* a year for stamp-duty, and drivers' and conductors' licences. Stage-coaches and omnibuses are not so severely taxed in other parts of the kingdom. In Ireland the road traffic is mostly conducted by means of Bianconi's stage cars—a remarkable example of successful and effective private enterprise.

STAINING. [DYEING; GLASS MANUFACTURE; PAPER HANGING.]

STAIRCASE. This is an indispensable part of the interior of buildings which consist of more than a ground-floor, and stairs of some sort must have always been employed wherever there were upper rooms, and even to obtain access to the terraced roofs which are used in the East. But we are altogether ignorant of the character of ancient staircases. Vitruvius—who touches upon so many matters that are very remotely connected with his subject—gives no information about staircases; neither has much light been thrown upon the subject by the discoveries of Pompeii. Scarcely any indications even of upper floors to the houses have there been found, and what few traces of staircases, or rather of stairs, remain, show them to have been exceedingly incommodious, fitted only for obtaining access to an upper loft, or to the roof, and not at all adapted for constant communication between dwelling apartments on different floors. It may, therefore, very safely be taken for granted—at least until some direct evidence to the contrary shall be found—that the houses of the ancients were in this, as well as in many other respects, greatly inferior to our own, and had nothing whatever corresponding to the modern staircase. Nearly the same may be said with respect to the ancient domestic architecture of our own country, where, even in residences of the highest class, the staircases were generally very confined, placed within turrets, and exceedingly steep and narrow: narrow not only as regards the actual width of passage up and down, but as regards the diameter or space occupied by the whole, there being no *well*, or central opening, but the steps winding around a solid newel; so that, in ascending or descending, a person is continually revolving, without any "foot paces" for resting upon, and cannot see whether he will encounter any one else. *Turnpike* was a term formerly applied to staircases of this kind; also *vise*, from their spiral or screw-like shape, whence the more modern appellation of *corkscrew* stairs, corresponding with the Italian *scala alla lumaccia*, or *scala alla chiocciola*, with the French *escalier à limaçon*, and the German *wendeltreppe*.

It was not till about the time of Elizabeth that staircases began to be planned more commodiously in this country, and were made a decorative feature in the interior of a mansion. But though they were greatly improved, the flights being made wider, and the steps parallel to each other, with intermediate landings or resting-places between the several flights, and although considerable decoration was bestowed upon them,—the walls being panelled, and the parapet of the stairs formed either by richly carved balusters or open fretwork, frequently with heraldic figures of animals on the pedestals at the angles of the different flights,—the staircase itself was usually inclosed within a comparatively small area, so as to admit of no general view of the whole of it, there being very little open space, or *well*, as it is termed, sometimes none at all. The staircases at Aldermaston, Berks; Crewe Hall, Cheshire; and Knole, Kent, may be taken as examples of the kind. At a later period, staircases in mansions of a superior class were made disproportionably spacious, being upon a scale as to size with which the apartments themselves were not at all in keeping.

The planning of a staircase is generally considered one of the most difficult matters in internal architecture, and it is certainly one that requires great consideration. Yet there is no particular difficulty, except where, as is generally the case in moderate-sized houses, the architect is cramped for room, more especially if, while restricted in that respect, the ascent from one floor to another is greater than usual. The number of stairs, and the space required for the convenient arrangement of them, are easily estimated when the height of the ascent from one floor to another is given, and the dimensions are determined for the risers and treads. Stairs are technically described as consisting of *risers* and *treads*, the former being the fronts or heights of the steps, and the other their flat surfaces or breadths. Stairs are further distinguished as being *flyers*, those which ascend straightforward; and *winders*, which having their treads triangular, coming quite to a point at their ends near the balusters, afford no footing there, and ought consequently to be avoided whenever it is at all practicable to do so. A *flight* is a consecutive series of stairs in the same direction, or between one *quarter-space* or *half-space* (*palier*) and another, which last are short intermediate landings, serving to lessen the fatigue of a continuous ascent, by subdividing it into shorter flights. For the area containing, or rather constituting, the staircase itself, we have no distinct term in addition to the general one, similar to the French *cage*, the Italian *gabbia*, and the German *treppenhaus*.

We proceed to notice the most convenient proportions of the stairs themselves as to height and breadth for their length. As to the breadth of the flights, that is comparatively arbitrary: it should never be much less than 4 feet, so as to allow two persons to pass, except in back-staircases; but it may be as much more as the space will permit, or the effect aimed at in the design may require. The best general, and what may be considered standard, proportions, are 6 inches for the risers and 12 inches for the treads; though from 6½ to 7 inches may be allowed for the former, and only ten for the latter, in secondary staircases. In those of a very superior kind, on the contrary, the risers do not exceed 5 or even 4 inches (less height than which last would be more fatiguing than convenient), and their treads are then made from 14 to 16 inches. The height, therefore, to the landing of the floor to be reached being given, it is easy to calculate either how many risers of a certain number of inches will be required; or what must be the dimensions of the risers and treads, in order to ascend within the space allowed. Supposing the first-mentioned height to be 14 feet, and the risers 6 inches, two risers will be equivalent to 1 foot of ascent, and consequently twenty-eight risers will be required, or twenty-seven treads, the upper landing being the tread to the last riser. In such case, hardly less than an area of 20 by 8 feet, on the level of the upper floor, would be sufficient for the staircase, unless there were winders instead of quarter-spaces, or of a single half-space between the two flights. The number of risers required is ascertained by reducing the given altitude of ascent to inches, and dividing it by the height of the risers: thus, taking the altitude as before (14 feet), and the risers at 5 inches, there must either be 33 risers a trifle more than 5 inches each, or 34 a trifle less. Rondelet gives the following very simple formula for calculating the dimensions of the treads and risers respectively, namely, calling h the riser, and t the tread, $2h+t=2$ feet; it is based on the principle that the ordinary length of a pace is equal to 2 feet, and that the effort exercised in lifting the leg vertically is double the effort required to move it horizontally.

Palladio, and others following him, have laid it down that the staircase ought to be seen immediately on entering a building; but it is impossible to establish any positive rule for what must depend upon particular circumstances, and this is by no means the best general arrangement. In a public building or place where strangers go in and out without inquiry, it may be desirable that the staircase should present itself at once; but certainly this is not the case in private mansions. On the contrary, it is in every respect better that the staircase should be kept out of view until the first vestibule has been passed through, and that it should be placed in a position as remote from the entrance into the house as the plan will admit, both in order that the approach to it may be lengthened, and that, in case it has any architectural pretensions at all, it may strike the more by not coming into view at once. At all events, only the lower part of the staircase —no more than is sufficient to indicate its situation—should be visible from the entrance, otherwise it will be inconveniently exposed; and if there are doors to several rooms on the upper landing, persons passing from one to the other would be seen from the hall. It is therefore a great error to place the staircase, as is sometimes done, in the first or entrance hall of a mansion, because, in addition to the inconvenience just pointed out, such hall must be made the height of two floors, and consequently, if otherwise suitably proportioned to such height, it will be the most spacious and loftiest room, and so far be attended by a degree of effect which, instead of being afterwards increased or kept up, is greatly diminished. Such arrangement also cuts off the communication above between the rooms on one side of the hall and those on the other, except there is a gallery or continuation of the landing carried over the entrance.

Even when kept apart from the entrance-hall or other vestibule, a staircase will always be sufficiently striking in proportion to the rest of a house, because it will produce greater architectural effect, and be loftier than the rooms themselves. We are now speaking only of what is usually termed a "grand staircase," leading up no higher than the principal floor, so that the whole of the space from the level of the landing is perfectly clear, and there are no flights leading up higher, for if there were, the space over head would appear encumbered and confused. There is in fact no part of an interior which accommodates itself more readily to architectural character and display, or which admits of greater variety of design both as to plan, section, and decoration, than a staircase of the kind just referred to. If the house itself be not upon a very large scale, there is danger of doing here rather too much than too little. In regard to altitude, there will here always be greater magnitude than elsewhere; if therefore corresponding magnitude of area be given to it, the staircase will overpower everything else, cause the rooms to appear small by comparison, and appear in itself too large for the house. It is therefore desirable to make the area, at least the visible area of the staircase, rather less than more than that of any of the principal rooms. It is also rather a solecism to affect magnitude of space in other respects corresponding to that of height. While it serves as a contrast to the apartments, loftiness or excess of height, as compared with length and breadth, is as much an appropriate characteristic of a staircase as it is of a tower. Its altitude therefore from the bottom of the first flight to the ceiling, may very properly be made between two or three times the breadth. Accordingly it will be found expedient to enclose the landing, if continued quite round the staircase, not merely by a screen of columns, but in such manner as to shut it out from view, with only partial openings at intervals, in order to avoid too much spaciousness on that level, and to keep the *cage* of the same size from bottom to top. Of such staircase upon a large scale there is an example at Taymouth Castle, the seat of the Marquess of Breadalbane, which is about 40 feet square by 100 feet in height, with an upper corridor surrounding it, with open arches.

One of the most simple and effective yet least common arrangements of a staircase, is that which may be described by the term *avenue staircase*, the stairs being continued in a straight line, though broken by *spaces* into a succession of flights, within what would else be a level corridor or gallery; and occupying its entire width. There is something particularly noble and majestic in a staircase of this kind, for although it may be narrow, considered as a gallery, it looks unusually spacious as a staircase, the *flight* itself being wider than those of staircases placed within a much larger area; besides which, the whole is more regularly disposed, and forms a more striking piece of perspective. Still, simple as such plan is in itself, it is by no means adapted to general application, because, although it requires only moderate width, it requires considerable length, short flights, and ample spaces between them, and stairs with low risers and broad treads; otherwise, the descent, as viewed from above, being in a straight line, looks precipitous, or at least has no dignity of appearance. Another circumstance which limits a staircase of this kind to particular cases, is, that in order for it to produce proper effect, the height to be ascended should be very moderate, hardly more than seven or eight feet; for else, the space at the foot of the stairs looks confined, and the upper flights scarcely show themselves from that station. Hence, though it may be referred to as an instance of an avenue staircase, the one leading to the keep or round tower at Windsor Castle, is more remarkable than beautiful or grand, leaving decoration out of the question; the altitude ascended being so very great. Sir John Soane has given some ideas of the kind in his designs for a 'Scala Regia'—a favourite subject with him. The staircase of the Chamber of Peers at Paris, designed by Percier and Fontaine, was an example of the kind, but not the best, for the ascent was so great that the columns on its sides, on the same level as the landing, looked quite insignificant. The National Gallery, again, afforded instances of a different modification of the same arrangement, half the ascent being by an external flight in the vestibule, the remainder by another within the corridor leading from it; and though not exactly suited for such a building, the idea is pleasing in itself and would produce a striking effect, in one of less pretension.

In public edifices or large mansions, whatever be the plan of the principal staircase, it is generally *branched*, that is, there is first a wide central flight, and then two other narrower ones branching off from it one on each side, either at right angles to it or as return flights parallel to it; and it is hardly necessary to observe, that in all such staircases the *foot-spaces* are large, and that there are no winders. Extreme care should, however, be taken in planning staircases of this (or indeed of any) description for places of public resort, as theatres, concert-rooms, &c., to so design them as to produce the least possible hindrance to the rapid passage of the audience in case of the occurrence of a panic. The branched staircase at Goldsmiths' Hall, which is parted off from the vestibule by a glazed screen, is an example of more than ordinary splendour, being lighted by a dome. The branching flights at right angles to the first, lead to a landing on each side, which has a double screen of Corinthian columns, so that the view across from side to side, in the upper part, is unusually rich. At Buckingham Palace, there is first a very wide flight, entered from between columns, branching off right and left in curved flights, the cage, which is about 36 by 26 feet, being curved elliptically on those sides or ends. In this example, the stairs rest upon a graduated podium or wall enclosing the space immediately beneath, which serves as a private passage behind; a mode frequently adopted in similar cases, being one which contributes to solidity and nobleness of appearance, and prevents that mass of shadow beneath the stairs which gives a gloom to the lower part of the staircase.

Instead of there being a central flight below, the ascent frequently begins on each side, and is carried up in one or more flights to the common landing, where both branches terminate; from which point the stairs are sometimes continued, returning in an upper central flight, which is carried across an arch thrown from that landing or half space, to a higher landing. Staircases of this kind, which may be termed *bridge* staircases, occur in the Custom House and the Auction Mart. Their effect, however, is not good, because the upper suspended flight or *bridge* darkens the lower part of the staircase, and has a strangely awkward cumbersome appearance when viewed from that station. At the best, therefore, they are suitable only for places of evening resort, where they can be lit up below as well as above.

The staircase of the Fitzwilliam Museum, Cambridge, claims notice, not only on account of the richness of the general design, but of some peculiarities in its arrangement. Strictly speaking however, this example can hardly be given as that of a staircase, according to the usual meaning of the term, the stairs being mere flights of steps in the entrance hall. That in the centre is a broad descending one, leading down to the libraries, which are on a lower level than the hall; and on each side of it is a rather narrower ascending flight to the spacious landing carried around three sides of the hall, and serving as a statue gallery. Though the lower area is only 32 by 26 feet, consequently that of the floor very much less, owing to the space occupied by the flights of steps, that of the upper part on the level of the landing is 68 by 44 feet, the landing itself being about 17 feet wide. In some degree similar in plan, although very different in design, is the hall at Holkham, the seat of the Earl of Leicester, which has a noble flight of steps within a recess or tribune enclosed by columns which are continued along the sides of the hall.

The grand staircase of the Reform Club-house, London, is an example, somewhat unusual in this country, though common enough in Italy, of what may be called an *enclosed* staircase; the flights are shut up between walls, and consequently there is no open *well*, nor can the whole be seen at one view. A plan of this kind therefore differs from the avenue staircase, merely in not being carried straight-forward, but either returning in a parallel flight from the half-space or first landing, or having the second flight at right angles with the first. The last is the case at the Reform Club-house, where the staircase consists of three enclosed flights, the last being a return one to the first, and landing upon the gallery around the upper part of the inner hall or saloon. That at Burleigh too is similarly planned. The same mode may be adopted for circular or semi-circular as well as rectangular plans; and one advantage attending it is, that while the ascent itself is as spacious and commodious as if the whole were entirely open, there may be a secondary staircase for servants, shut up within the larger one.

The architectural effect of a staircase will greatly depend upon the mode of lighting it. Where it is carried up only one floor, the best mode is to light it entirely from above, either through a dome or lantern in the ceiling, or by making the upper part of the walls just beneath the ceiling a continued lantern. If there are windows on the landings of the several flights, the effect will be improved by their being filled with stained glass, especially if towards a back court; or, if a conservatory can be carried out on the level of the first landing, so as to show itself through glazed folding-doors, a very pleasing and cheerful effect is obtained, even though the conservatory itself should be hardly more than a glazed veranda. As to material, stone is greatly preferable to wood for stairs, if only on account of greater security in case of fire; in lieu of stone, cast-iron may be employed. Marble is very rarely used for stairs in this country, and whenever it is, it should be left unpolished on the treads, or it would be dangerous to descend them. The same remark applies to stairs of wainscot, unless they are carpeted nearly their entire width.

STALL-FEEDING. The feeding of cattle in stalls for the purpose of fatting them more readily than by simple grazing, and at a time when they cannot get fat on pastures, as a regular part of the process of husbandry, is comparatively modern. In former times cattle were slaughtered in October and November, which latter, in most languages derived from the Teutonic, is called *Slaughter-month*, there being no possibility of buying fresh meat of any degree of fatness during winter, and salt meat was the food of all classes in that season. But now the process of fatting cattle goes on without interruption during the whole year, and fat beasts come as regularly to market in winter as in summer. Stall-feeding is now the principal means by which oxen and cows are rendered fit for the market.

It has been observed, in the article SOILING, that one object of that system was to save the waste of food which is occasioned by the treading of cattle in pastures, and by their choosing the sweetest grasses to the neglect of the coarser. The principal object however is to save the manure, which in the pastures goes to waste, but in the yards or stall is all preserved. In stall-feeding another object is looked to, that of increasing the substance of the animal, especially the fat; and to do this judiciously and with profit requires much experience and attention. It has been proved that animals require a certain portion of meat and drink to keep them alive, and that this quantity, in the same species, is in general in proportion to the weight of the animal. If an animal has his exact ration of food, he will continue in health, but he will not increase in weight: in this case therefore it only produces a certain portion of manure, which is not equivalent to the food consumed. If a larger quantity be given, the animal, if in health, will increase in weight, and the more food he has, within a certain limit, the faster will be this increase: but there is a point where increase stops; and if by any means the animal is induced to take more, his stomach will be deranged, and he will become diseased, and occasion loss by over-feeding. It is consequently of great importance to the stall-feeder to ascertain what is the exact quantity of food which it will be most profitable to give to a stall-fed animal. Experience alone can teach this: but some rules may be given which will enable any one who wishes to stall-feed cattle not greatly to err in his mode of feeding, and soon to find out what is the most profitable course to pursue. For this purpose it is essential that after having ascertained by experiment the quantity of food which will give the greatest increase of flesh per week on a certain weight of beasts when put up to fatten, all the food given to the cattle be carefully weighed, and no more be given in any day than is needful. The quality of the food should also be attended to; for a truss of fine well-made clover, lucern, or sainfoin hay, may contain double the nourishment of another truss of coarse marsh hay. The best kind of food should always be reserved for fatting cattle. Roots alone are too watery, and must be corrected by dry food, such as straw cut into chaff, or good hay, and especially farinaceous food, whether it be corn ground or bruised, or oil-cake. By a judicious mixture of food a much greater increase of flesh may be produced than by an irregular mode of feeding, however good the quality or abundant the quantity given may be. To overfeed is as unprofitable as to starve a beast, and produces similar effects. It is of great importance that the cattle should be fed with great punctuality, at certain hours during the day, and that the troughs should be cleared of all the remains of food which they do not eat at each time of feeding. Rest and sleep are great aids to digestion, and a little gentle exercise after sleep prepares the stomach for a fresh supply of food. Air also is highly conducive to health; and hence those beasts which are allowed to move about in a loose stall, or a small yard protected from the rain and wind, thrive better in general than those which are tied up. It is the practice of many good feeders to put oxen in pairs in small stalls, partly open, so that they may be in the air, or under shelter, as they prefer; and the finest oxen, if not the fattest, are prepared for the market in this way. Experience shows that all domestic animals like company, and that they are more contented and quiet when they have a companion than when they are alone. This is the reason why they are put up in pairs. Whatever promotes the health and comfort of the animal will be most profitable to the feeder. When a beast has acquired a certain degree of fatness, it is a nice point to decide whether it would be best to send him to market or continue to feed him. This is often decided by mere caprice or fancy; but if the food has been weighed, and the weekly increase of the beast is noted, which is best done by weighing, but may nearly be guessed by measuring, it becomes a mere question in arithmetic to determine whether his increase pays for his food and attendance; if it does not, there is a loss in keeping him; and if a lean animal put in his stead would increase faster on the same food, every day he is kept there is a loss of the difference between the increase of the two. The pride of producing a wonderful animal at a fair or show may be dearly paid for, and must be put down to the account of luxuries, like the keeping of hunters or racehorses.

The most profitable food for fattening cattle is, in general, the produce of the farm: the expense of all purchased food is increased by the profit of the dealer and the carriage of it. And the only compensation for this additional cost may be in increasing the manure, where the straw and roots of the farm are deficient: in that case oil-cake, or even corn, may be purchased with advantage, since by means of the manure crops may be raised which without it must fail. The stalling of cattle, as well as the fatting of pigs, is in many situations the best means of carrying the produce of the farm to market. An ox can be driven many miles, whilst the food he has consumed would not repay the carriage, and all the manure would be lost, and must be purchased at a great expense, if it can be had at all. If a farmer can feed cattle, so as to pay him a fair market-price for the food consumed, and something for the risk of accidental loss, he may be well contented to have the manure for his trouble: few stall-feeders get more than this in the long run.

It may be proper to add to the above, that the box-feeding where the animal is loose in a space about 10 feet square, is more conducive to health than stall-feeding where the animal is tied by the neck. The box is littered every morning, and the animal is thus kept dry and clean without the removal of the soiled litter, which thus kept from exposure to air and rain, ultimately yields a much more fertilising manure than that of the ordinary dung-heap.

STAMMER. The terms stammer and stutter are synonymously adopted to denote the involuntary interruption of utterance arising from difficulty and often total inability to pronounce certain syllables, the speech apparatus being frequently affected with spasm in the effort to speak.

In some stammerers the spasm consists of involuntary movements similar to *chorea* (St. Vitus's dance), which occasionally affects other than the speech muscles. Stammer with this spasm distorts the utterance by an involuntary repetition of some part of the syllable, as ge-ge-ge-good de-de-de-day. The repetitions may or may not be vocal. In other stammerers the spasm consists of involuntary immobility, similar to *tetanus* (lock-jaw), commonly of the form termed *trismus*, in which the mouth is closed, and the jaw cannot move to open it; and sometimes of the form termed *antitrismus*, in which the mouth is open, and the jaw is equally incapable of moving to shut it. Stammer with this spasm distorts the utterance by an involuntary extension of some part of the syllable, as l——augh, where the *l* is much prolonged.

In the looseness of language resulting from inexact knowledge, all kinds of difficult and defective utterance are misnamed stammer; as the difficult utterance of the intoxicated, the faltering utterance of the paralytic, the imperfect utterance of deep emotion, as of fear, the defective utterance of malformed organs of speech, and the hesitation in discourse when the suitable word fails to present itself to a speaker's mind. Such affections of the utterance, however, are distinct from stammer, for

1. The stammerer's inability to pronounce words remains during health, soberness, calmness of mind, and also when the appropriate words occur to him.

2. The stammerer feels his difficulty of utterance essentially to consist in a refusal of some part of the speech apparatus to obey his will.

3. The stammerer's utmost efforts to force out any difficult word commonly excite spasm, and increase it if it previously existed.

4. The stammerer's inability to speak is intermittent: the same syllable is not always equally difficult to utter, and is sometimes uttered with ease.

Those circumstances will distinguish stammer from the misnamed stammer of paralysis, intoxication, &c.

Now, to understand the nature of stammering, it is necessary to know the audibility and mechanism of utterance, which may be thus briefly described:—

The voice is produced in the larynx, whence it issues into the pharynx. The pharynx opens into the nose and into the mouth; and by means of a curtain valve, named the *velum pendulum palati*, we can direct the issue of breath through the mouth or the nose, or through both mouth and nose at once. The voice is produced in the larynx, an audible sound, which may possess the distinctions of song-notes (musical sounds), as those of pitch, loudness, and quality; or it may possess the peculiar conditions of those distinctions which constitute speech notes. In the pharynx and mouth the volume of voice is magnified, and its quality is modified.

Observation and experiment concur to prove that the production of voice is an acoustic phenomenon depending on mechanical principles similar to those which regulate the production of sound from an inanimate instrument; for it is now agreed that the upward current of air passing through the larynx produces an effect on the vocal ligaments precisely similar to what it would if the larynx were an inanimate mechanism. The voluntary power over the larynx adjusts it to be acted on by the current of air, and thus the voice is to be regarded partly as a mechanical and partly as a physiological result.

Observation and experiment concur to prove that the modification of voice into speech is also an acoustic phenomenon depending on principles similar to those which regulate the modification of sound by an inanimate instrument; for it is now agreed that the modification of voice into speech in passing through the variable cavity of the pharynx, mouth, and nose, produces an effect precisely similar to what would be produced if the variable cavity were an inanimate mechanism.

Thus both in voice and speech the production and modification of vocal sound depend on the laws of acoustics, while the adjustments of the various parts of the apparatus which produce and modify the voice depend on voluntary muscular movement. The one is mechanical, the other physiological.

It is familiarly known that the movement of every organ is effected by muscular contraction; that both voluntary and involuntary contraction of the muscles depend on the nerves; that all voluntary contraction is regulated by the brain; and also that the voluntary contraction of one muscle is accompanied by an adjusted voluntary relaxation of its antagonist muscle.

The speech apparatus may be considered as consisting of the lungs or bellows, which can send a current of air through the trachea or windpipe to the larynx, which is situated on its summit. In the larynx this current of air can be vocalised at will into song, or into speech-sounds, which, on passing through the variable cavity, consisting of the mouth, pharynx, and nose, can be further modified into speech. Thus the speech-apparatus, as a whole machine, consists of the respiratory, the vocal, and the enunciative organs.

The respiratory apparatus consists of the chest, the lungs, and the air-passages. The respiratory movements are involuntary and periodic; the inspiration of breath alternates with its expiration; and in both acts the breath flows in a continuous stream. There is a periodic action of the inspiratory muscles, but whether their action alternates with an action of the expiratory muscles, or simply with the spontaneous return of the parts by their elasticity and gravity, is yet undetermined. The muscular actions during the tranquil respiration of repose appear to be limited to periodic inspiratory movements.

The movements of respiration include the motions of the diaphragm, the abdominal and thoracic muscles, and those of the larynx, which dilate and contract the aperture of the glottis. The nerves engaged in these movements are the phrenic, the spinal accessory, the vagus, many of the spinal nerves, and the portio dura of the seventh. The will can influence and somewhat modify the movements of respiration; thus we can prolong or shorten the duration of an inspiration, and we can delay or hasten to begin one. We have similar control over the expiration of the breath; and we have power also to limit, or nearly so, the movements of respiration to sub-groups of muscles: thus we can breathe by the diaphragm alone, or by the ribs alone.

Indeed in the act of vocalising, whether for speech or song, the involuntary is almost superseded by the voluntary act of respiration. The will gives a different play to the chest. We breathe less by the diaphragm and more by the ribs; we shorten the duration of the inspiration and completely change the character of the expiration.

There are two modes of involuntary respiration: in the one, the breath issues in one continuous unbroken stream, as in the ordinary breathing of unruffled tranquillity, which by some emotions is hurried and involuntarily vocalised, producing sighs, groans, &c.; in the other mode the stream of breath is interrupted so that it issues in detached portions, which during some emotions is also involuntarily vocalised, producing laughter, crying, &c.

The will has power to produce voluntary expirations in both modes. The unbroken stream is termed the exhausting breath, which is often required for a long-drawn note in song. The broken stream is termed the holding breadth, which is constantly required in lengths suitably adjusted to the demands of the syllables as they occur in speech. The general conditions of respiration, vocalisation, enunciation, and articulation, under which stammer occurs, are subjoined.

I. *Respiration.*—1. Most stammerers manage their respiration badly, although nearly all can speak freely in a whisper. 2. They feel that they have insufficient breath to speak. This sensation, however, arises less from an insufficiency than from attempting to speak on an involuntary inspiration. The breath is expired to be vocalised by the voluntary action of the ribs, which mechanically contract the chest's cavity. The ribs, however, cannot accomplish this when they are in the position in which an involuntary inspiration leaves them; they must be raised to that position to which a voluntary inspiration carries them, before they can act with mechanical effect on the chest to expire a holding breath for the purpose of conversation. 3. With the sensation of insufficiency of breath, some feel also a pain at the pit of the stomach. This pain is connected with attempting to speak on an involuntary inspiration, and its severity is commonly increased by struggling to speak.

II. *Vocalisation.*—1. *Song-voice.* The song condition of voice seldom presents any difficulty to stammerers. Cases of stammer in the song-voice occur but rarely.

2. *Speech voice.*—Stammer occurs in all parts of the speech-note, more frequently, however, in the middle than towards the end, but most commonly at the initial.

3. *Pitch of Voice.*—Changes of pitch, whether concrete or discrete (slide or skip), through narrow intervals of the scale, present difficulties which wider changes of pitch do not. Stammerers can mostly declaim, if they cannot converse or quietly read; and it is well known that wider intervals of pitch occur in declamation than in ordinary conversation.

4. *Loudness of Voice.*—When the loudness of the speech-note is of the form of the musical *diminuendo*, which begins abruptly and gradually diminishes in loudness, as thus figured $>$, a difficulty is presented to the stammerer which does not occur if the form be the musical *crescendo*, where the note begins feebly, and gradually increases in loudness, as thus figured $<$.

5. *Quality of Voice.*—The conversation tone presents a greater difficulty than the falsetto, or than the full enriched voice of epic declamation.

6. *Quantity or Duration of Syllables.*—Short and inextensible syllables present a greater difficulty than the long and extensible.

7. *Accent.*—The unaccented syllables of discourse seldom offer any difficulty to stammerers. The element, or combination of elements, which is difficult to utter with accent, is easy to utter without accent. The accent given by stress is infinitely more difficult than that given by extended duration.

8. *Rhythmus.*—The measured movement of verse is easier for the stammerer than the unmeasured movement of prose and conversation.

III. *Enunciation.*—Syllables are of two kinds, namely :—

1. Those composed of one elementary sound.
2. Those composed of more than one elementary sound.

1. *Vowels.*—A vowel alone may constitute an accented syllable, and even a whole word, of which the pronoun *I* and the article *a* are familiar examples. Stammer often occurs on such syllables.

2. *Consonants.*—When two or more are combined together without a vowel to form a syllable, they occur only as unaccented final syllables of words. The stammerer's difficulty is less to utter the elementary sounds singly than to articulate them so as to form syllables.

IV. *Articulation.*—The elementary sounds are articulated in three orders of succession :—

1. The vowel followed by a consonant.
2. The consonant followed by a vowel.
3. The consonant followed by a consonant.

Stammer occurs in each of these modes of articulation. There is seldom any difficulty in articulating two consonants together; some, however, is felt in postfixing a consonant to a vowel, and the greatest is felt in adding a vowel to a consonant.

To these general conditions of voice and speech under which stammer occurs, may be added other conditions, such as sex and age. A majority of stammerers are males; and few of either sex stammer from their infancy; children commonly speak freely until about five years of age. An occasional difficulty is first observed, which becomes more frequent up to the tenth year, when it is commonly at its maximum; although the spasm frequently increases in severity up to manhood. In the decline of life sometimes the stammer spontaneously diminishes, and it has been known to entirely disappear. The voices of childhood and old age differ in several respects from that of the intermediate period of life. The speech melody of infancy is set in a high pitch, which often runs into the falsetto, and is much intersected with wide intervals both concrete and discrete. The loudness is chiefly of the *crescendo* form on long whining quantities. The voice of old age often falls into the tremulous scale, the rate of utterance is slow, steady, and uniform. The loudness is not often of the *diminuendo* form, and is on extended quantities. The accent is given to syllables by quantity rather than by stress, deliberate pauses are made, and the whole style is marked by the self-possession of experienced age conversing with a consciousness of superiority, if in nought else, in a longer reach of memory. Sudden changes of temperature, especially from a high to a low temperature, likewise tend to increase a stammer.

The *Varieties of Stammer* are many. They all arise from—1. Difficulty to produce voice; 2. Difficulty to produce voice in quantities adjusted to the syllable's demands; 3. Difficulty to produce the elementary sounds; 4. Difficulty in joining such sounds together; and in each of these classes there are varieties.

Variety 1 arises from ill-regulated respiration, in which the effort to vocalise is accompanied with a feeling of insufficiency of breath. The stammer proceeds from an attempt to speak on an involuntary inspiration. A holding breath cannot be maintained on an involuntary inspiration, and therefore voluntary respiration for speech must always begin with an inspiration of breath. The physiology of this stammer indicates a discipline for its removal. The organs of respiration must be drilled to rightly change the involuntary act of respiration to the voluntary, which, with a course of rhythmus, will effect a permanent cure.

2. The difficulty in producing voice which is occasioned by an involuntary closure of the glottis. In this variety of stammer, instead of the larynx receiving the adjustment for vocalisation in ready obedience to the will, the glottis suddenly closes, either by an involuntary associate movement, or by a tetanic spasm, probably in most cases by the latter. Dr. Arnott pointed out the nature and means to cure it. His remedy consists in keeping open the glottis, by issuing a drone sound, such as the *e* of the word berry, before beginning to speak, and in joining this prefixed drone to the words. See his 'Elements of Physics,' vol. i.

3. The difficulty in producing voice which is occasioned by an involuntary twitching of the glottis similar to chorea. This spasm is sometimes so excited as to preclude vocalisation, when only short iterations of breath are audible. The glottis must be disciplined on sounds of the *crescendo* form of loudness in a low pitch, and proceed gradually from the song-voice to that of speech. Respiration and speech-voice training will follow, accompanied with general rhythmic discipline to the whole speech-apparatus for reading and speaking both verse and prose.

4. In this variety the difficulty is not to produce voice, but to control its quantities. Vocalisation freely takes place, but the event of two or three short or accented syllables following near together throws the glottal muscles into choreal spasm. The principles of discipline for the spasm will be similar to the preceding variety of stammer; while a distinct discipline must be projected to acquire a higher degree of associating power.

5. The difficulty of uttering a vowel of uniform sound is a voice stammer, it being an absence of voluntary control over the vocalisation of the breath. The difficulty of uttering a diphthongal vowel may be either a voice or a speech stammer, and is often a combination of both. When the difficulty is to produce voice to begin the vowel, the stammer is vocal; and when the difficulty is to change the adjustment from that for the initial, to that for the final sound of the diphthong, it is a speech stammer. When the difficulty is to produce voice to begin the consonant, the stammer is vocal; and when the difficulty is to change the adjustment from that for the initial to that for the final sound of the consonant, it is a speech stammer. Stammer on the single elementary sounds of speech can be permanently remedied only by a systematic training of the disobedient organ which occasions it. The organ must be disciplined to perform the necessary movements under all conditions of voice, which, accompanied with a general training of the whole apparatus of speech, conducted on rhythmical principles, will effectually remove the stammer.

6. Stammer occurs in all three modes of articulation, namely :—

A consonant followed by a vowel, as *bee;* a vowel followed by a consonant, as *ebb;* a consonant followed by another consonant, as *bl* of the word *bled.*

The difficulty in articulating the elementary sounds of speech to form syllables, can be permanently remedied only by a systematic training of the disobedient organs to perform their required movements for the several adjustments of the mouth which are necessary to articulation. The training must be general and special. The general is a rhythmic training of the whole speech-apparatus; and the special is a training of the disobedient organ to perform its various movements in articulation.

Our analytic description of stammering reveals three functional causes of inability to control the muscular movements which are required for utterance, namely :—

I. Spasm, both of the tetanus and chorea forms. All muscles are liable to spasm. Spasm of the larynx, the tongue, the lips, and the masseter muscle, are each sources of stammering.

II. Defect in the associating power, which combines the voluntary movements of different organs in one simultaneous act, or in an allied succession of acts. Defective association of vocalisation with respiration will occasion stammer; for perfect association of the voluntary movements of the larynx with those of the chest are required in utterance. The movements of the larynx and chest are effected by means of the laryngeal, the recurrent, and the expiratory nerves.

III. Involuntary associate movements; as after mimicking a stammerer it has been found that those muscular movements, which in the mimicry were *voluntarily* associated with the proper movements of utterance, have suddenly become linked to them so firmly in allied motion, that the mimicker is unable to dissociate them, and an actual stammer results.

The adoption of appropriate remedies for stammering then will depend on the following conditions, namely :—1. On the part of the speech-apparatus which is affected; 2. On the cause producing the stammer; and 3. On the vocal and other conditions under which the utterance is least affected. The appropriate remedies for each are treated of in several works on the subject, among which we may mention Thelwall's 'Letter to Clive on Stammering;' Cull's 'Observations on Impediments of Speech;' Cull's 'Stammering Considered;' and J. Hunt's 'Treatise on the Cure of Stammering.'

STAMPING, STAMPING PRESS. The important manufacturing process of stamping will be found sufficiently described in several foregoing articles in this work; such as BRASS; BUTTON; CHASING; COPPER; MINT; NEEDLE, &c. In most varieties of the operation, the substance to be treated is in the form of a thin sheet. The pattern is engraved on two dies, one placed below and one above the plate; and the impression is given by the upper die being made to fall forcibly upon, or being forcibly driven into, the plate. The lower die is generally a reverse of the upper, the one being in cameo and the other in intaglio; that is, any part of the device which is convex or raised in the one, is concave or sunk in the other.

STAMPS, STAMP ACTS. Stamps are impressions made upon paper or parchment by the government or its officers for the purposes of revenue. They always denote the price of the particular stamp, or in other words, the tax levied upon a particular instrument stamped, and sometimes they denote the nature of the instrument itself. If the instrument is written upon paper, the stamp is impressed in relief upon the paper itself; but to a parchment instrument the stamp is attached by paste and a small piece of lead which itself forms part of the impression. These stamps are easily forged, and at various times forgeries of them upon a large scale have been discovered. The punishment for the forgery of stamps was long a capital offence; it is now punishable by imprisonment or penal servitude.

In France stamps are used both for the authentication of instruments and as a source of revenue: thus they constitute a large part of the income of the municipality of Paris.

The stamp tax was first introduced into this country in the reign of William and Mary, such an impost having previously existed in Holland. The act 5 W. & M., c. 21, imposes stamps upon grants from the crown, diplomas, contracts, probates of wills and letters of administration, and upon all writs, proceedings, and records in courts of law and equity; it does not however seem to impose stamps upon deeds, unless these are enrolled in the courts at Westminster or other courts of record. Two years afterwards, however, conveyances, deeds, and leases were subjected to the stamp duty, and by a series of acts in the succeeding reigns every instrument recording a transaction between two individuals was subjected to a stamp duty before it could be used in a court of justice. By the 38 Geo. III. chap. 78, a stamp duty was imposed on newspapers (which was only taken off a few years ago), [Newspapers], and by an act of Geo. IV., inventories and appraisements are required to be stamped. Stamps are also used as a convenient method of imposing a tax upon a particular class of persons: thus, articles of apprenticeship are subject to duty, and so are articles of clerkship to a solicitor. Solicitors and conveyancers are required to take out annually a stamped certificate, and before a person commences practice as a physician, an advocate, a barrister-at-law, or an attorney, he must pay a tax, under the form of a stamp upon an admission. Notaries public, bankers, pawnbrokers, and others must obtain a yearly licence in order to exercise their callings.

It is only possible thus generally to point out the nature of the things subject to stamps, as these have varied frequently, and are subject indeed to constant change. It is enough to refer to the stamps on newspapers and letters as an example. And it may be added here that it is only recently that the system of levying a tax by means of stamps on legal proceedings has been revived, after having been abandoned for a great many years.

The general principle which regulates the courts in the interpretation of the stamp acts is, that on the one hand fraudulent evasion of the stamp duties shall be punished by forfeiture of all benefit from the document which ought to have been stamped; and, on the other hand, that a just claim shall not be evaded or a fraud be effected because the just claimant has unintentionally violated the stamp laws. Accordingly almost all instruments requiring stamps (except bills and notes) may be stamped on payment of a penalty; and all courts of civil justice are authorised to receive the unstamped instrument when tendered in evidence, on deposit of the amount of the stamp and penalty. Bills and notes cannot be stamped after they are made; a provision intended to prevent fraud in the use of these important instruments of commerce.

An unstamped instrument, though in general inadmissible, may be used as evidence to defeat fraud, and, with certain limitations, to establish a criminal charge. Thus, where an unstamped agreement contained matter not requiring a stamp, it was used as evidence of that matter, although invalid as evidence of the terms of the agreement. An indictment for forgery likewise may be maintained, although the instrument forged may be invalid for want of a proper stamp; but such an invalid instrument is not sufficient to support an indictment for larceny.

The stamp duties and the custody of the dies are placed under the superintendence of commissioners, who transact their business in Somerset House, London. It may not be out of place to remark that the endeavour to impose stamp duties upon our American colonies in 1765, was one of the proximate causes of the American revolution.

STANAMYL. [Organometallic Bodies.]

STANDARD OF MEASURE, &c. [Weight, Measure, &c., Standard of.]

STANDARD TEMPERATURE AND PRESSURE. In determining the specific gravity of solids and liquids, the standard of comparison is the weight of an equal bulk of distilled water at 60° Fahr.; and for gases and vapours atmospheric air is the standard at 60° Fahr., and under a pressure of 30 inches. In France the standard temperature is 0°C. (32° Fahr.), and the pressure is 760 millimètres, or 29·922 inches. The unit of density is the volume of an equal bulk of water, at its point of maximum density, namely, 39°·2 Fahr. [Specific Gravity; Heat.]

STANDARDS are those trees or shrubs which stand singly, without being attached to any wall or support. In gardening and planting they are distinguished into three kinds, the full standard, the half standard, and the dwarf standard. The full standards are trees whose stems are suffered to grow seven or eight feet or more without allowing side branches to be developed, but at this point are allowed to spread in all directions. In this way most fruit-trees, with the exception of the vine, may be grown, though many of those of the almond tribe, as the peach, apricot, &c., are best grown against a wall. The various kinds of apple, pear, and plum trees are grown as full standards. In fruit-trees the primary branch or stem is often cut off at a certain height for the purpose of favouring the lateral growth; but in forest-trees grown for the sake of timber or for ornament, this treatment is never resorted to.

Half standards are those plants which are allowed to run up three or four feet and then permitted to branch out. The height at which it is desired a tree should branch out may be frequently secured by cutting off the lower branches up to that point, or by cutting down the primary branch and allowing the highest lateral branches to developе themselves. Many shrubs grow naturally in this manner, and when fruit-trees are grown in this way, it is done as a matter of convenience for gathering the fruit, or ensuring their growth under particular circumstances.

Dwarf standards are those plants whose stems are only allowed to reach a height of one or two feet before they are permitted to branch, and this object is effected in the same manner as in the last. All kinds of fruit-trees, as apple, pear, plum, and cherry trees, may be grown as dwarf standards, but these trees do not bear so good fruit under such treatment as when allowed to grow as half or full standards. Gooseberry and currant trees are best treated in this way, and when care is taken to thin them well, they produce by far the finest fruit when grown as dwarf standards of about a foot high. It is in this way that the fruit of the gooseberry has been brought to so great perfection in Lancashire and elsewhere. Many shrubs may be trained as dwarf standards, although in most instances they are more ornamental when allowed to grow as bushes with several stems direct from the ground.

STANETHYL. [Organometallic Bodies.]

STANMETHYL. [Organometallic Bodies.]

STANNARY, from the Latin *Stannum*, "tin." This term sometimes denotes a tin-mine, sometimes the collective tin-mines of a district, sometimes the royal rights in respect of tin-mines within such district. But it is more commonly used as including, by one general designation, the tin-mines within a particular district, the tinners employed in working them, and the customs and privileges attached to the mines, and to those employed in digging and purifying the ore.

The great stannaries of England are those of Devon and Cornwall, of which the stannary of Cornwall is the more important. The stannary of Cornwall, and also that of Devon, were granted by Edward III. to the Black Prince, upon the creation of the duchy of Cornwall, and are perpetually incorporated with that duchy. Both stannaries are under one duchy-officer, called the lord warden of the stannaries, with a separate vice-warden for each county.

All tin in Cornwall and Devon, whoever might be the owner of the land, appears to have formerly belonged to the king, by a usage peculiar to these counties. King John, in 1201, granted a charter to his tinners in Cornwall and Devonshire, authorising them to dig tin and turves to melt the tin anywhere in the moors and in the fees of bishops, abbots, and earls, as they had been used and accustomed. (Madox, 'Exch.,' 279 t, 283 l.) This charter was confirmed by Edward I., Richard II., and Henry IV.

In Cornwall the right of digging in other men's land is now regulated by a peculiar usage, called the custom of *bounding*. This custom attaches only to such land as now is or anciently was *wastrel*, that is, land open or uninclosed. By this mode the bound-owner acquires a right to search for and take all the tin he can find, paying the lord of the soil one-fifteenth, or to permit others to do so; and to resist all who attempt to interrupt him. The bounds must be renewed annually, by a bounder employed on behalf of the bound-owner, or the lord may re-enter.

As part of the stannary rights, the duke of Cornwall, as grantee of the crown, has or had the pre-emption of tin throughout the county, a privilege supposed to have been reserved to the crown out of an original right of property in tin-mines, but which in modern times is never exercised.

The stannary courts were remodelled by the 6 & 7 Wm. IV. c. 106. The duties payable to the duke of Cornwall on the stamping or coinage of tin were abolished by 1 & 2 Vict. c. 120; and further regulations for these courts were introduced by 2 & 3 Vict. c. 58; and the jurisdiction was extended, and the procedure amended and improved by the 18 & 19 Vict. c. 32.

STANNIC ACID. [Tin.]

STANNIC ETHYLOMETHIDE. [Organometallic Bodies.]

STANZA (*Stance*, in French), an Italian word which means room or dwelling-place, is used in poetry to designate certain parts or divisions of a poem, each forming a complete period within itself, and consisting of a number of lines regularly adjusted to each other, and containing every variation of measure or rhyme which is to be found in the whole poem. There is a great variety of stanzas in the poetry of modern languages, according to the rhythm and structure of the poem. There is the terzina of three lines, used chiefly by the Italians and Spaniards; the quartetto (quatrain, in French) of four lines; the sestina, "sixain," of six lines; the ottava, consisting of eight lines, used in epics, &c. Each of these is susceptible of various combinations of measure and rhyme.

STAPHISAGRIA, or **STAVESACRE**, the seeds of the *Delphinium staphisagria*. [Delphinium, in Nat. Hist. Div.] Stavesacre seeds are not now used internally: when introduced into the stomach they cause vomiting, purging, and local ulceration of the intestines, and they may even produce serious general effects. When powdered, they are employed externally for the destruction of lice, or they are dissolved in vinegar and made into an ointment, which is employed for the cure of scabies, which it is said to effect in seven or eight days, and which has found favour in the eyes of some persons, as it does not stain the linen, nor have the unpleasant smell of sulphur. Its external application to abraded surfaces is not free from danger. The only case in which its employment is justifiable is, not to remove, but cause revulsion of, the cutaneous eruption, when, by its sudden drying up, the internal organs are oppressed, as, like most ranunculaceous plants, it causes acute inflammation and pustulation of the skin. It contains an alkaloid, delphine [Delphine], which is a powerful sedative against rheumatic and neuralgic pains. Its internal use requires great caution, and still more its external use as a lotion or ointment, as its absorption through chaps, cracks, or ulcerated places, makes an impression on the nervous system more dangerous than when taken into the stomach. A volatile acid also exists in it, which is powerfully emetic. As this is dissipated at a low temperature, decoction is an objectionable form of administration.

STAPLE, "anciently written *estaple*, cometh," says Lord Coke, "of the French word *estape*, which signifies a mart or market." It appears to have been used to indicate those marts both in this country and at Bruges, Antwerp, Calais, &c., on the Continent, where the principal products of a country were sold. Probably in the first instance these were held at such places as possessed some conveniences of situation for the purpose. Afterwards they appear to have been confirmed, or others appointed for the purpose by the authorities of the country. On the Continent in the staple-towns the goods had to be offered there for sale, and if not bought within a prescribed time might be again exported on payment of a certain toll, and the towns had to provide warehouses where the goods were to be deposited. This rule, however, has been materially modified, and in many cases abolished. In England the arrangement of the staple was made by the king (2 Edw. III. c. 9). All merchandise sold for the purpose of exportation was compelled either to be sold at the staple, or afterwards brought there before exportation. This was done with the double view of accommodating the foreign merchants, and also enabling the duties on exportation to be more conveniently and certainly collected. Afterwards the word staple was applied to the merchandise itself which was sold at the staple. The staple merchandise of England at these early times, when little manufacture was carried on here, is said by Lord Coke to have been wool, woolfells or sheepskins, leather, lead, and tin. Incident to the staple was a court called "the court of the mayor of the staple." This court was held for the convenience of the merchants, both native and foreign, attending the staple. It was of great antiquity; the date of its commencement does not appear to have been certainly known. Many early enactments exist regulating the proceedings at the staple and the court held there. Most of these were passed during the reigns of the two Edwards, the first and the third of that name. These kings appear to have been extremely anxious to facilitate and encourage foreign commerce in this kingdom; and by these statues great immunities and privileges are given, especially to foreign, but also to native merchants attending the staple. The first enactment of importance is called the statute of merchants, or the statute of Acton-Burnel, and was passed in the 11th year of Edw. I. A.D. 1283. [Acton-Burnel, Statute of.] But the statute more expressly directed to this subject was passed in the 27th year of Edw. III. cap. 8, and is entitled the Statute of Staple. One object of it was to remove the staple, previously held at Calais, to various towns in England, Wales, and Ireland, which are appointed by the statute itself.

Matters connected with the staple were not subject to the cognisance of the king's courts, and the king's officers were prohibited from interfering in places where the staple was held. The court consisted of a mayor, who was to be acquainted with the law merchant, and was elected every year by the merchants attending the staple, both native and foreign; he was attended by two constables, also elected by the merchants, and who held their office for life. Two alien merchants, one, as the statute says, "towards the north," probably a German, "the other towards the south," Italian, were to be chosen to be associate in judgment with the mayor and constables, and also six mediators of questions between buyers and sellers. Of these six persons, two were to be Germans, two Lombards, and two English.

In matters of doubt reference was to be had to the privy council. The mayors, sheriffs, and bailiffs of the towns where the staple was held, or there adjoining, were also to attend the mayor and ministers of the staple to execute their commands. Complaints against the mayors were to be redressed by the chancellor and others of the privy council. A prison also was to be provided for the use of the staple, and the mayor and constables had power given them to keep the peace, and to arrest and imprison, their authority extending throughout the town in which the staple was held and the suburbs of it.

The law administered in the court of the staple, so far as regarded all matters connected with the staple, was the law merchant [Lex Mercatoria], and not the common law of the land, nor the custom of the place. If both parties in a suit were foreigners, all the jury were to be foreigners. If one party was native, the other foreign, the jury was to be half native, half foreign. Upon the judgment of the court execution was to be done in the manner provided for by the statute merchant. The statute contains various other enactments relating to the internal regulations of the staple.

Several other statutes were passed in the same and succeeding reigns, in some respects confirming, in others altering the provisions of the leading statute. As commerce became more extended, the staples appear to have fallen into disuse. Lord Coke, a great worshipper of antiquity, complains that in his time the staple had become a shadow; we have only now, he says, stapulam umbratilem, whereas it was formerly said that wealth followed the staple. The practice, however, of taking recognisances by statute staple, from the many advantages attending them, long continued. (11 Edw. I.; 27 Edw. III. caps. 1, 3, to 6, 8, 9; 2 *Inst.* 322; *Com. Dig.* tit. 'Stat. Staple;' 2 Saund. by Wms. 69; Reeves, *Hist. Eng. Law*, v. 2, pp. 161, 393.)

STAR, DOUBLE STAR. We distinguish the stars from the planets in much the same way as our ancestors did before us, though there is hardly one point of difference which is now left to its full extent. A contemporary of the publication of the 'Principia' (1687), engaged in writing an article like the present, would have stated that the only notion out of which antiquity described a star was derived from its fixedness in the heavens; to which he would have added that these stars present no appearance of systematic arrangement, that their distance is too great to be measured, and that they exert no sensible attraction on the solar system. Not one point of this is now left except the last: the speculation described in Milky Way gives a high probability to the theory that the universe is a collection of vast systems of stars; observations of double stars have rendered it certain that many organised systems, regulated by mutual attraction, exist in space, besides our solar system; it is fully established that numbers of stars, once called fixed, have slow motion of their own in the heavens; and in a few instances at least there is no room left for doubt that [Parallax of the Fixed Stars] the distance of the stars has been approximately ascertained. That no discoverable effect of attraction upon our system can be traced, is the only point in which the stellar astronomy of our own day coincides to the full extent with that of the time of Newton.

The apparent motions of the stars are first to be cleared of the effects of Precession and Nutation, and also of Aberration, which depend on motions of our earth, as well as of the grand diurnal revolution. From the Refraction of our atmosphere, and from the various casualties to which the rays of light are subject in passing through it, proceed, besides the increase of apparent altitude alluded to in the article cited, a great many varieties of colour and general appearance, particularly that decided size which most of the stars appear to have. A good telescope reduces this phenomenon very much, in favourable states of the atmosphere; but even these instruments are not so perfect as to show the stars to be what there is no doubt they ought to be, mere luminous points. If the apparent diameter of 61 Cygni, the earth's atmosphere being entirely removed, were only one-third of a second, or one-thirtieth of that of Venus when smallest, it is now known that the diameter of that star must be equal to that of the earth's orbit.

Independently of relative position, the stars are distinguished by their colour and quantity of light, on which last in a great degree depends their apparent magnitude. A casual observer would hardly think that there was any difference of colour between one and another; but a little practice shows that a tinge of one or another colour predominates a little in the nearly white light which all the stars have in common; and a good telescope gives some stars an appearance which observers have not scrupled to call "blood-red." And when the two stars of a close double star are together in the field of a telescope, it most frequently happens that each star differs sensibly in colour from the other. But when we look at a star, we must remember that we see only the result of the treatment which its light has received from the atmosphere; and with a telescope the matter is in some respects worse, for there is no object glass which forms anything like a real image. "When we look at a bright star," says Sir John Herschel, "through a very good telescope with a low magnifying power, its appearance is that of a condensed brilliant mass of light, of which it is impossible to discern the shape for the brightness; and which, let the goodness of the telescope be what it will, is seldom free from some small ragged appendages or rays. But when we apply a magnifying power from 200 to 300, the star is then seen (in favourable circumstances of tranquil atmosphere, uniform temperature, &c.) as a perfectly round well-defined planetary disc, surrounded by two, three, or more alternately dark and bright rings, which, if examined attentively, are seen to be slightly coloured at their borders. They succeed each other nearly at equal intervals round the central disc, and are usually much better seen, and more regularly and perfectly formed, in refracting than in reflecting telescopes. The central disc too is much larger in the former than in the latter description of telescope. These discs were first noticed by Sir William Herschel, who first applied sufficiently high magnifying powers to telescopes to render them visible. They are not the real bodies of the stars, which are infinitely too remote to be ever visible with any magnifiers we can apply; but *spurious* or unreal images, resulting from optical causes, which are still to a certain degree obscure." The various appearances of stars, as seen in telescopes, particularly the resolution of stars which appear single into two or more, render them excellent objects, when classified, for the examination of the power and goodness of these instruments. Such a classification was made by Sir J. Herschel ('Mem. Astron. Soc.'); and the paper is reprinted at the end of the explanation (published separately) of the maps of the stars published by the Society for the Diffusion of Useful Knowledge.

The magnitude of a star is a notion formed by observers as to the apparent quantity of light which comes from them, on which they are divided into classes. Those which are visible to the naked eye are usually divided into six magnitudes, which, according to W. Herschel, emit quantities of light which are (roughly) in about the proportions of the numbers 100, 25, 12, 6, 2, and 1. But though practical astronomers are tolerably well agreed as to the mode of naming most of the principal stars in respect of magnitude, there are many about which they differ, and some as to which it is tolerably well known that the order of magnitude which adherence to old catalogues still procures for them, is not that which would have been given had they been new stars named in our day. The magnitudes of stars are in fact rather indeterminate after the first and second. An astronomer would hardly say that an appearance was like a star of the "first or second" magnitude; the difference of the two is too well established, though as to the fainter stars of the first magnitude, and the brighter ones of the second, there may be little to choose between them. But it is very common to speak of an appearance as being of the "second or third," "third or fourth," &c., magnitude, showing that the distinction between one magnitude and the next is not then very prominent. Sir John Herschel and Professor Struve, the two most assiduous observers of small magnitudes, usually differ ('Mem. Astron. Soc.,' vol. iii. p. 180) about a magnitude in their estimation of one star with another, from and below Struve's fourth or Herschel's fifth magnitude, down to Struve's twelfth or Herschel's thirteenth. When therefore the reader, who is no astronomer, hears of the constant reference to stars of all magnitudes down to the sixteenth, he must look upon it as a rough mode of estimating the relative brilliancies of the stars, in which a numerical nomenclature is far from being held to imply numerical accuracy.

Some stars (perhaps all) are variable in their magnitudes, and with periodical regularity, which is perhaps to be attributed to the effect of revolution round their axes; it being imaginable that different parts of a star should give different kinds or quantities of light, either or both. [Variable Stars.]

There are a few instances in which a sudden appearance of a new star is recorded, followed, after a time, by its disappearance. Such a phenomenon made an astronomer, it is said, of Hipparchus; and certainly the star which appeared in Cassiopeia in 1572 was the introduction of Tycho Brahé to the character of a public astronomer. [Brahé, Tycho, in Biog. Div.] Tycho Brahé himself thought, from historical evidence, that a star had appeared in Cassiopeia in 945 and 1264, that of his own time being in 1572, from which, if the historical evidence be correct, a new star might be expected to appear in that constellation in 1872 or thereabouts. But, on examining his evidence, we find it exceedingly vague and deficient in antiquity. ('Comp. to Maps of the Stars,' p. 86.)

It has been reasonably supposed that those stars which have most motion are comparatively near to the earth, and when it was requisite to choose a double star for the determination of the question of Parallax, 61 Cygni was selected, as being a star with a large proper motion; in fact, its right ascension alters yearly 5″·46, and its declination 3″·19. The experiment turned out favourably, and the parallax was discovered, and with it (roughly) the distance of the star from the solar system. And though light takes more than ten years to travel from this star to the earth, at the rate of two hundred thousand miles a second; yet, so far from this being anything enormous, it rather cuts down the idea which was entertained of the distance of these bodies. The absence of all parallax, in spite of repeated efforts to obtain it, made many speculations upon the possibility of the nearest starlight being hundreds of years in reaching us. Among other stars which have a decided proper motion, we may notice Sirius, Procyon, 61 Virginis, α Bootis, A Ophiuchi, ρ Ophiuchi, and μ Cassiopeiæ.

The particular objects which are seen in the heavens are *stars*, simple points of light, and *nebulæ*, patches of an appearance of cloudy light. Single stars, under the telescope, very frequently become double, triple, quadruple, or even a large cluster; nebulæ are in some cases found to consist entirely of stars, but many remain which either are not composed of stars, or will not show themselves as such to the power of our present telescopes. It is necessary to say, in speaking of double stars, that they have been long known to exist, and that scores of observers have been diligently employed upon them during the last century and a half.

When two stars are so close together that the naked eye shows them only as one, it is possible that the coincidence may be merely optical; that is, that the lines of their directions may be so close as to make an apparent coincidence, such as takes place between the sun and moon in an eclipse of the former, though the real distances may be very great. Such optical coincidence is suspected in various double stars, but only a long course of observation can settle the suspicion in either way. But it is now found that many double stars are connected with each other by the law of gravitation, each revolving in an ellipse about their common centre of gravity, and showing every evidence of each being retained by the other, according to the Newtonian law of gravitation. The following stars, γ Leonis, ε Bootis, ζ Herculis, δ Serpentis, and γ Virginis, were made out to be revolving double stars, by W. Herschel, in 1803. He had been examining these pairs under the idea of detecting the parallax from them, and in so doing he recognised their changes of relative position. Since that time, Castor, ξ Ursæ, 70 Ophiuchi, σ Coronæ, η Coronæ, ξ Bootis, η Cassiopeiæ, δ Cygni, μ Bootis, ε (4) and ε (5) Lyræ, λ Ophiuci, μ Draconis, ζ Aquarii, ζ Cancri, and others, have been added to the list. The periods of revolution of several have been determined, ranging from 43 to 1200 years, and the other elements of several orbits have been established. The star η Coronæ has completed a revolution since it was first observed.

The most interesting of double stars is γ Virginis. When observed by Herschel in 1780, the distance between the two constituent stars amounted to 5″·66. Henceforward it continued gradually to decrease, until at length, in 1836, the two stars had approached so close as to appear like one star even when observed in the best telescopes. From that time the two stars have been slowly opening out from each other, until they are now nearly 4″ apart. The orbit of this double star has been computed by several astronomers, including among these Sir John Herschel, who has found the period of revolution to be 182 years. The orbits of a considerable number of double stars have been computed in recent years, a list of which will be found in Herschel's 'Outlines of Astronomy' and other similar works. The most distinguished observers of double stars besides the elder Herschel have been Sir John Herschel, Sir James South, the Rev. Mr. Dawes, and Admiral Smyth, in this country; and on the continent the elder Struve, Bessel, Professor Mädler, Otto Struve and Professor Secchi. The labours of the elder Struve in this field of astronomical observation exceed in magnitude and importance those of any other astronomer.

STAR-CHAMBER. The Star-Chamber is said to have been in early times one of the apartments of the king's palace at Westminster allotted for the despatch of public business. The Painted Chamber, the White Chamber, and the Chambre Markolph, were occupied by the triers and receivers of petitions, and the king's council held its sittings in the Camera Stellata, or Chambre des Estoylles, which was so called probably from some remarkable feature in its architecture or embellishment. According to Sir Thomas Smith's conjecture "either because it was full of windows, or because at the first all the roofe thereof was decked with images or starres gilded." ('Commonwealth of England,' book iii. cap. 4.) Sir William Blackstone proposes a conjecture that the chamber received its name from its having been a place of deposit for the contracts of the Jews, called "Itarrs," under an ordinance of Richard I. (Blackstone's 'Commentaries,' vol. iv. p. 266, note.) Whatever may be the etymology of the term, there can be little doubt that the court of Star-Chamber derived its name from the place in which it was holden. "The lords sitting in the Star-Chamber" is used as a well-known phrase in records of the time of Edward III., and the name became permanently attached to the jurisdiction, and continued long after the local situation of the court was changed.

The judicature of the court of Star-Chamber appears to have originated in the exercise of a criminal and civil jurisdiction by the king's council, or by that section of it which Lord Hale calls the *Consilium Ordinarium*, in order to distinguish it from the *Privy Council*, who were the deliberative advisers of the crown. (Hale's 'Jurisdiction of the Lords' House,' chap. v.; Palgrave's 'Essay on the Original Authority of the King's Council.') This exercise of jurisdiction by the king's council was considered as an encroachment upon the common law, and being the subject of frequent complaint by the Commons, was greatly abridged by several acts of parliament in the reign of Edward III. It was discouraged also by the common-law judges, although they were usually members of the council; and from the joint operation of these and some other causes the power of the Consilium Regis as a court of justice had materially declined previously to the reign of Henry VII., although, as Lord Hale observes, there remain "some straggling footsteps of their proceeding" till near that time. The statute of the 3 Henry VII. c. 1, empowered the chancellor, treasurer, and keeper of the privy-seal, or any two of them, calling to them a bishop and temporal lord of the council and the two chief justices, or two other justices in their absence (to whom the president of the council was added by stat. 21 Henry VIII., c. 20), upon bill or information exhibited to the lord chancellor or any other, against any person for maintenance, giving of liveries, and retainers by indentures or promises, or other embraceries, untrue demeanings of sheriffs in making panels and other untrue returns, for taking of money by juries, or for great riots or unlawful assemblies, to call the offenders before them and examine them, and punish them according to their demerits. The object and effect of this enactment are extremely doubtful. It appears to have been the opinion of the courts of law at the time the statute was passed that it established a new jurisdiction, entirely distinct from the ordinary jurisdiction of the council; for five years afterwards, in the eighth year of Henry VII., it was resolved by all the judges, according to the plain words of the law, that the only judges of the court under the statute were the lord chancellor, the treasurer, and the keeper of the privy-seal, the bishop and temporal lord being merely "called to them" as assistants or assessors, and not as constituent members of the court. ('Year Book,' 8 Hen. VII., 13, pl. 7.) This view of the effect of the statute is confirmed by the fact that, more than forty years afterwards, the president of the council was expressly added to the judges of the court by the statute 21 Henry VIII., c. 20; "a decisive proof," as Mr. Hallam observes "that it then existed as a tribunal perfectly distinct from the council itself." ('Constitutional History,' vol. i., p. 70.) And this writer concludes a careful examination of the subject by the following propositions: "1. The court erected by the statute of 3 Henry VII. was not the court of Star-Chamber, 2. This court by statute subsisted in full force till beyond the middle of Henry VIII.'s reign, but not long afterwards went into disuse. 3. The court of Star-Chamber was the old *Concilium Ordinarium*, against whose jurisdiction many statutes had been enacted from the time of Edward III. 4. No part of the jurisdiction exercised by the Star-Chamber could be maintained on the authority of the statute of Henry VII." In the first of these propositions, Mr. Hallam is confirmed by Hudson, in his 'Treatise of the Court of Star-Chamber.' ('Collectanea Juridica,' vol. ii. p. 50.) On the other hand, both Lord Coke and Lord Hale consider the statute of Henry VII. as having merely introduced a modification of the ancient jurisdiction. The former calls the above resolution of the common-law judges "a sudden opinion," and says it is "contrary to law and continual experience." And he contends that the statute did not create a new court, but was merely declaratory of the mode of proceeding in an ancient court, previously known and recognised. ('Fourth Institute,' p. 62.) Lord Hale also speaks of the "erection of the court of Star-Chamber by the stat. 3 Henry VII.," and says it "was a kind of remodelling of the *Consilium Regis*." ('Jurisdiction of the Lords' House,' chap. v., p. 35.) However this may have been, there is no doubt that, previously to the time of Coke, this court, whether distinct or only a modification of the ancient jurisdiction, had again merged in the general jurisdiction of the lords of the council so completely as to justify his statement, that the opinion expressed in the judicial resolution was "contrary to continual experience." Sir Thomas Smith, who wrote his 'Treatise on the Commonwealth of England' in the year 1565, makes no mention of a limited court, though he treats particularly of the court of Star-Chamber, and says that the judges were the lord chancellor, the lord treasurer, all the king's council, and all peers of the realm; and he ascribes the merit of having renewed the vigour of the court to Cardinal Wolsey. At the beginning of the reign of Elizabeth, therefore, the court of Star-Chamber was unquestionably in full operation in the form in which it was known in the succeeding reigns; and at this period, before it had degenerated into a mere engine of state, it was by no means destitute of utility. It was the only court in the land in which great and powerful offenders had no means of setting at defiance the administration of justice or corrupting its course. And during the reign of Elizabeth, when the jurisdiction of the Star-Chamber had reached its maturity, it seems, except in political cases, to have been administered with wisdom and discretion. (Palgrave's 'Essay on the King's Council.')

The proceedings in the court of Star-Chamber were by information, or bill and answer; interrogatories in writing were also exhibited to the defendant and witnesses, which were answered on oath. The attorney-general had the power of exhibiting ex-officio informations; as had also the king's almoner to recover deodands and goods of a felo-de-se, which were supposed to go in support of the king's alms. In cases of confession by accused persons, the information and proceedings were oral, and hence arose one of the most oppressive abuses of the court in political prosecutions. The proceeding by written information and interrogatories was tedious and troublesome, often involving much nicety in pleading, and always requiring a degree of precision in setting forth the accusation which was embarrassing in a state prosecution. It was with a view to these difficulties that Lord Bacon discouraged the king from adopting this mode of proceeding in the matter of the pursuivants, saying that "the Star-Chamber without confession was long seas." (Bacon's 'Works,' vol. iii. p. 372.) In political charges, therefore, the attorney-general derived a great advantage over the accused by proceeding *ore tenus*. The consequence was, that no pains were spared to procure confessions, and pressure of every kind, including torture, was unscrupulously applied. According to the laws of the court, no person could be orally charged, unless he acknowledged his confession at the bar, "freely and voluntarily, without constraint." (Hudson's 'Treatise of the Court of Star-Chamber.') But this check upon confessions improperly obtained seems to have been much neglected in practice during the later periods of the history of this court. Upon admissions of immaterial circumstances thus aggravated and distorted into confessions of guilt, the Earl of Northumberland was prosecuted *ore tenus* in the Star-Chamber, for being privy to the Gunpowder Plot, and was sentenced to pay a fine of 30,000*l.* and to be imprisoned for life; "but by what rule," says Hudson ('Coll. Jurid.,' vol. ii.), "that sentence was, I know not, for it was *ore tenus*, and yet not upon confession." And it frequently happened during the last century of the existence of the Star-Chamber, that enormous fines, imprisonments for life or during the king's pleasure, banishment, mutilation, and every variation of punishment short of death, were inflicted by a court composed of members of the king's council, upon a mere oral proceeding, without hearing the accused, without a written charge or record of any kind, and without appeal.

The judges of the court of Star-Chamber were the lord chancellor or lord keeper, who presided, and when the voices were equal gave a casting vote, the lord treasurer, the lord privy seal, and the president of the council, who were members of the court *ex officio*, probably by usage since the statute of 3 Henry VII. In addition to these, were associated, in early periods of the history of the court, any peers of the realm who chose to attend. According to Sir Thomas Smith, the judges in his time were the "lord chancellor, the lord treasurer, all the king's majesty's council, and the barons of this land." ('Commonwealth of England,' b. iii. c. 5.) Hudson states that the number of attendant judges "in the reigns of Henry VII. and Henry VIII. have been well near to forty; at some one time thirty; in the reign of Queen Elizabeth often times, but now (that is, in the time of James I.) much lessened, since the barons and earls, not being privy councillors, have forborne their attendance." He further states, that "in the times of Henry VII. and Henry VIII. the court was most commonly frequented by seven or eight bishops and prelates every sitting-day;" and adds, "that in those times, the fines trenched not to the destruction of the offender's estate, and utter ruin of him and his prosperity, as now they do, but to his correction and amendment, the clergy's song being of mercy." ('Coll. Jurid.,' vol. ii., p. 36.) The settled course during the latter part of the reign of Elizabeth and the reigns of James I. and Charles I. seems to have been to admit only such peers as judges of the court as were members of the privy council.

The civil jurisdiction of the Star-Chamber comprehended mercantile controversies between English and foreign merchants, testamentary causes, and differences between the heads and commonalty of corporations, both lay and spiritual. The court also disposed of the claims of the king's almoner to deodands, as above referred to, and also such claims as were made by subjects to deodands and *catalla felonum* by virtue of charters from the crown. The criminal jurisdiction of the court was very extensive. If the king chose to remit the capital punishment, the court had jurisdiction to punish as crimes even treason, murder, and felony. Under the comprehensive name of contempts of the king's authority, all offences against the state were included. Forgery, perjury, riots, maintenance, embracery, fraud, libels, conspiracy, and false accusation, misconduct by judges, justices of the peace, sheriffs, jurors, and other persons connected with the administration of justice, were all punishable in the Star-Chamber.

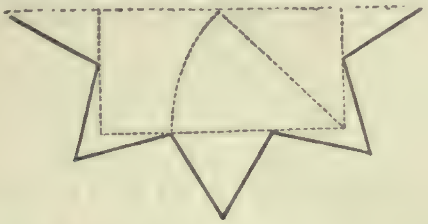
It was also usual for the judges of assize previously to their circuits to repair to the Star-Chamber, and there to receive from the court directions respecting the enforcement or restraint of penal laws. Numerous instances of this unwarrantable interference with the administration of the criminal law occur with reference to the statutes against recusants in the reigns of Elizabeth and James I.

A court of criminal judicature, composed of the immediate agents of prerogative, possessing a jurisdiction very extensive, and at the same time imperfectly defined, and authorised to inflict any amount of punishment short of death, must, even when best administered, have always been viewed with apprehension and distrust; and, accordingly, in the earlier periods of its history we find constant remonstrances by the Commons against its encroachments. As civilisation, knowledge, and power increased among the people, the jurisdiction of the lords of the council became more odious and intolerable. A measure which was introduced into the House of Commons in the last parliament of Charles I., to limit and regulate the authority of this court, terminated in a proposal for its entire abolition, which was eventually adopted without opposition in both houses. The statute 16 Car. I. c. 10, after reciting Magna Charta and several early statutes in support of the ordinary system of judicature by the common law, goes on to state that "the judges of the Star-Chamber had not kept themselves within the points limited by the statute 3 Henry VII., but had undertaken to punish where no law warranted, and to make decrees having no such authority, and to inflict heavier punishments than by any law was warranted; and that the proceedings, censures, and decrees of that court had by experience been found to be an intolerable burthen to the subjects, and the means to introduce an arbitrary power and government." The statute then enacts, "that the said court called the Star-Chamber, and all jurisdiction, power, and authority belonging unto or exercised in the same court, or by any of the judges, officers, or ministers thereof, should be clearly and absolutely dissolved, taken away, and determined, and that all statutes giving such jurisdiction should be repealed."

STAR-FORT, a kind of redout inclosing an area, and having its lines of rampart or parapet disposed, on the plan, in directions making with each other angles which are alternately salient and re-entering, as a star is usually represented. This construction is adopted when the work is intended to contain, for some time, the stores of an army, or to secure some important part of the position which the army occupies. The magistral line of the work may be traced by first laying down a polygonal figure, regular or irregular, as the ground may permit, and then upon each of its sides forming an equilateral triangle: the interior capacity and the quantity of fire will evidently be increased as the polygon has a greater number of sides; but the importance of the work is seldom so great as to render it necessary to form it on a polygon superior to a hexagon or an octagon; and the latter polygon, while it admits of being easily traced, allows the re-entering angles between the sides of the triangles to have a degree of obtuseness sufficient to avoid the risk that the defenders of the faces on each side of such an angle might fire upon one another. As it is found that soldiers fire nearly perpendicularly to the face of the parapet behind which they stand, a greater obtuseness would cause the lines of fire to diverge so far from the direction of the adjacent face as to prevent the ditch of the latter from being effectually flanked.

A star-fort on an octagon may, if the ground is level, be traced by laying down a square, and, upon the middle of each of its sides, an equilateral triangle, whose base is one-third of the length of such side; or, more regularly, by transferring half the diagonal of the square to each side, from the four angles; the distances between the extremities of these half diagonals are the sides of an equilateral octagon, and upon these sides equilateral triangles may be formed. The subjoined cut represents the magistral line of half a star-fort with eight points, constructed in this last manner. If the polygon had more than twelve sides, the re-entering angles would be acute; and, agreeably to the above supposition concerning the direction in which soldiers fire, the defenders on the adjacent faces might annoy one another.

That the fire of musketry may be sufficiently effective, it is considered proper that the lengths of the several faces should not be less than thirty yards; and a star-fort whose faces are of much greater length is capable of containing a garrison more numerous than that which would be required for the end proposed by such a work. A star-fort with six or eight points has a great advantage over a simple redout, though its construction is less simple: the crossing fires from the faces seriously impede the advance of the enemy towards the salient points; and the assailants, in passing the ditch, are completely exposed to the view of the defenders.



During the Seven Years' War, the king of Prussia's intrenched camp at Jauernick contained a star-fort on a rising ground in its centre, from whence the movements of the Austrians could be observed; and in this work the king's tent was pitched. The position taken up on the Nivelle by Marshal Soult, while the British army was acting in the south of France (1813), was protected by a strong star-fort. The work was constructed on a terrace below the summit of a mountain called the Smaller Rhune, and was intended to defend the entrance of a ravine. A platform below the summit of a ridge of high ground near the Bidassoa was, in like manner, fortified by a star-fort.

STARCH ($C_{12}H_{10}O_{10}$). *Fecula; Amidon; Amylaceous matter.*—The substance known in commerce and in domestic life as starch, is usually prepared from wheaten flour. *Starch*, however, exists in abundance in very many other vegetables, so that, strictly speaking, the term is a generic one. The flour of barley, oats, rye, arrow-root, sago, tapioca, rice; the greater part of the common potato, harico bean, lentil, maize, millet, &c., is starch. The starch from these various sources is identical so far as composition is concerned; the elements carbon, hydrogen, and oxygen exist in exactly similar proportions in all. As usually met with, the several varieties differ somewhat in taste, but this is probably owing to admixture of traces of volatile oil. [ESSENTIAL OILS, *of Starch.*] They appear also to slightly differ from each other in capability of assimilation when taken as food; a fact not yet satisfactorily accounted for.

To the naked eye starch presents a white glistening appearance, and seems to be an aggregation of small shapeless particles. By the aid of the microscope, however, it is seen to consist of beautiful regular ovoid granules; and under a magnifying power of from two to five hundred diameters, each granule is found to be marked by a series of circles converging from the circumference to a point termed the hilum. The size of the granule, the distinctness of the concentric lines, and the position of the hilum, are always the same in any one kind of starch, but vary considerably in starch from various sources; the microscope is therefore of considerable aid in detecting the admixture of an inferior with a superior variety, and in determining the origin of a starch.

Starch is insoluble in, and but very slightly acted upon by, cold water; nor is it really soluble in hot water. When, however, it is heated with twenty or thirty times its weight of water its granules swell and finally burst; if the whole be diluted and set aside, the rent walls of the granules subside to the bottom of the containing vessel, while their contents are so thoroughly mixed with the water that the two can only be separated by very tedious processes. Starch is also insoluble in alcohol or ether. Acids and alkalies, even when cold and highly diluted, cause it to swell and form a paste and finally convert it into dextrin. Air-dried starch usually contains about eighteen per cent. of water; if more than this is present the starch has a tendency to agglutinate when pressed between the finger and thumb; moreover, when projected on to a metal plate heated to 212° Fahr., it agglomerates into hard lumps forming a sort of artificial tapioca, no such effect being produced if it has been properly air-dried. Exposed in vacuo at a temperature of 60° Fahr., the amount of water is reduced to fifteen per cent. ($C_{12}H_{10}O_{10}$, 2Aq.) and at 260° Fahr. to the minimum of eight and a half per cent. ($C_{12}H_{10}O_{10}$). At a higher heat than this, starch is converted into dextrin.

Starch combines with certain bases, the compounds have been termed *amylates;* that of lead contains ($C_{12}H_9O_9 + 2PbO$).

Test for Starch.—Free iodine communicates a deep blue colour to starch. The resulting body is called iodide of starch, but its constitution has not yet been satisfactorily ascertained. The colour disappears if the iodine be in excess, if the mixture be boiled, or if any unstable organic matter, such as urine, be added to it. By bringing iodide of starch into contact with yeast, M. Duroy has lately obtained what he calls colourless iodide of starch, a sweet, gummy, uncrystallisable neutral substance, very soluble in water, but insoluble in alcohol.

The amount of starch in various vegetables varies as they progress towards maturity, and is much influenced by soil and climate.

Wheat Starch.—Wheaten flour is mixed with water and exposed to the air, with occasional stirring, for several weeks. During this time a portion of the gluten of the flour undergoes putrefaction: fermentation is set up, and some of the starch is converted into carbonic acid and alcohol, acetic and lactic acids are also formed. During this change an exceedingly unpleasant prutrescent odour is given off from the mass; the starch, however, ultimately subsides in the pure state, and colourless, the other matters with which it was mixed in the flour, as well as some products of decomposition, remaining in solution or floating on the surface as a scum, called *slimes* or *flummery*. The latter was formerly given to pigs for food, but is now used by the calico-printer as a resist paste. The peculiar, but well-known columnar appearance of wheat starch, as met with in commerce, is acquired during the drying opertion. The moist starch is cut up into blocks about six inches square, and placed in carefully heated stoves; as the water evaporates the masses shrink and split up into the characteristic irregular fragments.

A preferable method of extracting starch from wheat-flour has lately been introduced by Mr. Martin. It consists in kneading the flour into dough with water, and then washing on a sieve in a stream of water. The starch is thus washed out, and nearly all the gluten remains behind as a sticky mass. Slight fermentation is induced in the washings, whereby the remaining portions of gluten are destroyed, and the starch is then dried. The gum-like gluten educed in this process is dried, ground, and sold as semolina, or is mixed with flour and made into maccaroni and similar pastes.

Potato Starch, now largely manufactured on the Continent, is readily obtained from the washed and rasped or grated potatoes by simple kneading of the pulp in a stream of water on an inclined plate or fine sieve; the starch is carried off by the water, is allowed to subside, and after one or two washings by decantation, is drained in boxes lined with felt, and dried on floors of plaster of Paris. Potato starch does not, in drying, assume the columnar form characteristic of wheat starch.

Rice Starch.—For the preparation of this variety the rice is macerated for twenty-four hours in a very weak alkaline solution, composed of nearly half an ounce of caustic soda to a gallon of water; it is then washed, drained, reduced to a pulp, and again macerated in a fresh quantity of soda-ley; after brisk agitation and a short repose the liquor, still containing the starch in suspension, is poured off from the vegetable fibre, which first deposits, and the starch, accumulated by subsidence, is finally dried in the usual manner. The object of this process is the solution of the gluten in the weak alkali. If the latter be carefully neutralised by sulphuric acid the gluten is deposited in flocks, and after washing may be used in the preparation of certain varieties of food, as before mentioned.

Other Materials for Starch.—Mr. Simmonds states that at Oswego, in New York State, starch is made on a vast scale from maize or Indian corn. There is one factory which covers nearly three acres, and which consumes 200,000 bushels of maize yearly, whence is obtained 4,000,000 lbs. of starch. Mr. Anderson, by a patent obtained in 1857, proposes so to treat maize as to obtain starch from one portion, and oil from a residue hitherto wasted. Frequent search is made for new materials whence starch may be obtained. So far back as 1796, the Society of Arts offered a prize medal for any novelties in this direction. The prize was awarded to Mrs. Gibbs of Portland, who obtained starch from the roots of the *Arum maculatum*—4 lb. from 1 peck. It was very pure, and was sold under the name of "Portland arrow-root." There is not much now made, because the rotation of crops prevents the wild arum from growing. In 1853, M. Bassot obtained a prize in France, for making starch from the *Fistillaria imperialis*, or *crown imperial;* he washes and rasps the bulbs, and obtains starch from them in the usual way. The plant grows well in France. M. Bassot estimates that 5000 lbs. of starch may come from an acre of land, and need not cost more than 4*s.* per cwt.—much cheaper than potato starch. In 1857, there was a great demand for horse-chestnuts in France, in consequence of the establishment of a factory at Nanterre for making starch from that source. Chestnut trees are very abundant in France, and the starch obtained from the fruit is said to be good.

The use of starch in the cotton manufacturing districts is very large. One print-work in Manchester consumed 6000 cwts. in 1859 A kind called *Glenfield* starch is, by a peculiar process, made semi-transparent, for use in stiffening net and lace.

Properties of Starch.—Starch, when pure, is nearly devoid of odour and taste, and is possessed of demulcent properties when boiled in water, with which it forms a hydrate of a jelly-like character. Its insipidity, however, hinders it from being very digestible in this state, or even when kneaded with cold water, and exposed to heat, to form biscuits. Its digestibility is greatly increased by fermentation, and hence bread or rusks are much more suitable to invalids than any unfermented preparations of flour. The best bread is formed by flour which contains the greatest proportion of gluten. The relative proportions of starch and gluten differ not only in the different cereal grains, but in the same species or variety, according to the season when they are sown, or the manure which has been applied to the land.

Starch exists in larger proportion in Carolina rice than in any other grain. Potatoes yield the purest starch. It is procured from them with great ease, by simply rasping down the potatoes over a sieve, and passing a current of water over the raspings. The water passes through the sieve milky with the starch. By rest the starch subsides; it is then two or three times washed with pure water, and afterwards allowed to dry.

The quantity of starch is at its maximum in the winter months, but as soon as the potato begins to sprout, the starch lessens, as does also the proportion of nitrogen, so that its nutritive properties are impaired. If, however, the process of isolating the starch be followed in the winter months, the result is, a sixth portion of the weight of the potatoes employed, in a condition fit not only for immediate use, but of easy transport, and capable of preservation for years.

Starches differ, according to their sources, in chemical composition, and certainly in their digestibility, as also in their nutritive properties, according as they are isolated or associated with other principles, such as gluten. Wheat-starch consists of $C_{12}H_{10}O_{10}$, while potato-starch consists of $C_{12}H_9O_9$. Arrowroot has no gluten associated with it, rice very little, potato only one-third what good wheat has. Thus while arrowroot is the most digestible, wheat is the most nourishing. Potatoes are neither nourishing nor digestible, being of all starches the most prone to run into acidity, and so distress weak stomachs. The consumers of rice and potatoes are remarked to be almost invariably pot-bellied, owing to the large quantity they are compelled to use. "To supply a given amount of carbon and nitrogen to the system it costs two and a half times as much to obtain it from potato as from bread." (Dr. Edward Smith.) These facts constitute a strong objection to the use of potatoes, either in their natural state, as when used at dinner, or when employed as a constituent of bread. Many persons have found their health strikingly improved by relinquishing the use of potatoes. It is difficult to detect the presence of potato-starch in bread. The motive for using it is that it takes up more water than wheat-flour. But this is a double disadvantage to the consumer, as he gets less nutritious material for his money, and has unhealthy acid generated in his stomach. The bread made with flour very moist is always inferior, from an alteration in the gluten, unfavourable to a perfect panification, and because such bread is very much more prone to become mouldy, by which its degree of wholesomeness is still farther impaired. (Dumas, 'Traité de Chimie appliqué aux Arts,' vol. vi. p. 391.)

The carefully devised and systematically conducted experiments of Dr. Edward Smith prove that "animals cannot live on starch, and yet it is not uncommon to find mothers with deficient milk giving to their infants arrowroot, or some of the fashionable preparations of corn, which consist almost entirely of starch freed from the important nitrogenous constituents, and using water instead of cow's milk, under the impression that the latter would be too rich a food. Such a course can only be a source of starvation," and a fertile source of mortality. (See 'Practical Deductions from an Experimental Inquiry into the Influence of Foods,' by Edward Smith, M.D., Dublin, 1860.)

The above are the more important kinds of starch. For information concerning starch from other sources see the names of the several plants in the NATURAL HISTORY DIVISION of this Cyclopædia. [ARROWROOT; SAGO; SALEP; TAPIOCA.]

STARCH GUM. [BRITISH GUM.]

STARS, DOUBLE. [STAR, &c.]

STARS, SHOOTING. [METEOR.]

STATE. [SOVEREIGNTY.]

STATER (*στατήρ, a standard* of value), or *Chrysus* (*χρυσοῦς, gold money*), was the name of a Greek gold coin, which, after being used from a very early period in some states, became, in the time of Philip II. and Alexander the Great, the general gold currency of Greece. It is said to have been first coined in Lydia, to which the origin of silver money also is attributed by an ancient tradition. (Herod. i. 94.) The stater of Crœsus seems to have been the first gold money seen in Greece. (Herod. i. 54.) No undoubted specimen of this Lydian stater is in existence. According to Böckh, it was formed of the pale gold or electrum (¾ gold and ¼ silver) contained in the sands of the Pactolus.

Of the better known gold coins, most were of the same standard of weight as the Attic drachma, the Attic silver having at a very early period obtained a general circulation throughout Greece, and being reckoned extremely pure. The stater was generally equal in weight to two drachmæ, and in value to twenty. This was the case with the Macedonian stater, which the influence of Philip and Alexander brought into general circulation in Greece, and which continued to be coined by the later Macedonian kings after the same standard, or very nearly so. Many specimens of it exist.

The average weight of the staters of Philip and Alexander is a little under 133 grains. An assay of a stater of Alexander, made for Mr. Hussey, gave 115 grains of fine gold and 18 of silver, with no alloy. The silver here ought not to be reckoned as an alloy, and therefore the coin is equivalent to 133 grains of fine gold. Our sovereign contains 113·12 grains of fine gold. Therefore this stater was worth $\frac{133}{113{\cdot}12}$ of a sovereign, or a very little more than 1*l.* 3*s.* 6*d.* If we calculate its value by the number of drachmæ it was worth, we find it only 16*s.* 3*d.* The reason of this is, that silver was much dearer in ancient times than it is now. The higher value of the stater is the true one, as no material change has occurred in the value of gold.

In the states of Greece proper the chief standards of money followed were those of Athens and Ægina. In both, the principal denominations of money were coined in silver, and it does not appear that the Æginetan system contained any gold coin.

At Athens there seems to have been no gold money in the flourishing times of the republic, if we except a coinage mentioned by the Scholiast to Aristophanes ('Frogs,' v. 719). There are however a few Attic gold coins in existence, but only about a dozen. Of these, three, which there is every reason to suppose genuine, are in the British Museum, and one in the Hunterian Museum at Glasgow. Their weights agree exactly with the Attic standard, being respectively 132·3, 132·7, 132·6, and 132·75 grains, or on the average 132·5875 grains, which is only about half a grain less than the Attic didrachm. The character of the impression is exactly like that of the old Attic silver, but the form of the coin is more like the Macedonian.

It is very clear however that foreign gold was in circulation at Athens quite as early as the Peloponnesian war. It was obtained doubtless in commerce, and as the tribute of the allies, many of whom had gold currencies. Among the denominations so used, the chief were the darics of Persia [DARIC] and the staters of the Greek cities of Asia and the neighbouring islands. In fact, the Greeks got nearly all their gold from Asia. The following were the principal coins of Greek states in circulation at Athens:—

Demosthenes (in 'Phorm.,' p. 914, Reiske) informs us that a little after 335 B.C. the stater of Cyzicus passed at Bosporus in the Tauric Chersonese for twenty-eight Attic drachmæ. The existing coins vary from 160 to 120 grains, the former of which is greater, the latter less than the Attic, and both apparently derived from an element of 40 grains. The existing coins seem however to have been multiples of different standards. As the heaviest of the existing coins does not come up to the weight answering to the value assigned to the Cyzicene stater by Demosthenes, we must suppose that gold was dearer or silver cheaper than usual at Bosporus at the time referred to.

The *Staters of Lampsacus*, which may be recognised by the impression of a sea-horse, are of the standard of the daric. Two in the British Museum weigh about 129 grains each.

The *Stater of Phocæa* also appears, from the specimens given by Sestini ('Degli Stateri Antichi'), to have followed the standard of the daric. It was divided into sixths (*ἕκται*) and twelfths (*ἡμίεκτα*), of which the latter were equal in value to eight obols, and in weight probably to one, since the obol bore the same proportion to the didrachm in the silver coinage, that the *ἡμίεκτον* did to the stater in the gold.

Most of the cities of Ionia coined staters. Those of Chios, Teos, Colophon, Smyrna, Ephesus, and other places, now exist. There were also gold coins struck in Samos, Siphnus, Thasos, the Greek cities of Sicily, and Cyrene, at an early period. After the Macedonian coinage of staters, many Greek states coined them according to the same standard; we may mention Epirus, Acarnania, Ætolia, and Syracuse.

The coins in the system of the stater were the single, double, and half staters; these were very common: there were also, less commonly, quarters, thirds, sixths, and twelfths of staters.

The Attic silver tetradrachm was called stater in later times, but it is doubtful whether it was so called in the best ages of the republic.

The term stater was also applied to weight, meaning apparently any standard of weight. The Mina and Sicilian Litra were so called.

(Hussey, *Ancient Weights and Money*; Wurm, *De Pond.*, &c.; Böckh, *Metrologische Untersuchungen*; Humphrey, *Coin Collector's Manual.*)

STATES-GENERAL. [NATIONAL ASSEMBLY.]

STATICS, a subdivision of mechanics, meaning the part of the science in which equilibrating forces are considered, in opposition to DYNAMICS, in which the effects of forces producing motion are investigated: it is subdivided into the statics of rigid and of fluid bodies, the latter being called HYDROSTATICS. The general considerations in MECHANICS, FORCE, PRESSURE, POWER, WEIGHT, &c., and such articles as LEVER, INCLINED PLANE, PULLEY, WHEEL AND AXLE, WEDGE, SCREW, may be consulted; and also the articles VIRTUAL VELOCITIES, THEORY OF COUPLES, &c.

One foundation of statics was first given by Archimedes, and another by Stevinus, as noticed in MECHANICS. The former is the more rigorous, the latter being open to some objections of a serious character. The discoveries of Galileo turned the attention of philosophers upon dynamical problems, and the very easy connection which exists between the statical and dynamical measure of forces caused the theory of statics to be founded, almost up to the present day, upon dynamical principles. The taste for the purer form of statics has however revived, and we imagine that from henceforward it will be customary to make this science stand by itself.

The two great propositions of statics are that of the LEVER, demonstrated in the article on that word, and that of the COMPOSITION of pressures, mentioned, but not demonstrated. Which of these shall be chosen as the foundation of the science, and how the other shall be deduced from it, are two points on which every writer on the subject should think much, as the character of his work in the eyes of others will, in a great measure, depend on his treatment of these parts of the subject. The method of Archimedes is, in our opinion, the soundest of all; but we say it without denying the possibility of exhibiting a direct statical proof of the composition of pressures which shall be equally satisfactory. In those which have hitherto been given, there is a want of distinction between the mathematical and physical assumptions: the student leaves off with no very clear perception how far the proposition is one of mathematics, and how far one of physics. There is a general dislike and distrust of these proofs, which is evidence almost conclusive against them: any one who would improve them should not leave off until he has not only made a better separation of the physical axioms from the rest, but has put it in a form in which such separation is exceedingly obvious. Till this is done, the proofs in question will only stifle opposition, while the proposition of Archimedes forces conviction. If there be anything likely to be misunderstood in the latter, it applies as much to the former in all the cases which we have seen. [SUFFICIENT REASON.]

Statics, like all other mechanical sciences, is usually placed among mixed MATHEMATICS. But the line which separates it from the pure sciences is almost imperceptible, and it would seem more reasonable to invent a third and intermediate distinctive term, than to place statics and electricity under the same name, to distinguish them from geometry. It would be easy to show that all which is common to geometry and statics, and not to electricity, is more extensive, more striking, and more easily described, than the little which is common to statics and electricity, and not to geometry. In fact, when we say that both statics and electricity are concerned with properties of matter as distinguished from space, we have stated the whole of the common tie by which the two sciences are united: while geometry and statics possess in common almost equal degrees of evidence in their axioms, altogether the same rigour of deduction, and strong analogies in their theorems. Mr. Whewell has contended for the alteration of the location of statics: but he carries the idea farther than we can follow him, for ('Mechanical Euclid,') he asserts that the axioms of statics are "self-evidently true," "not to be learnt from without, but from within." We may also refer to the same writer's 'History of Scientific Ideas,' vol. i., 1858. We shall enter further upon this point in the article SUFFICIENT REASON.

STATIONARY (Astronomy). All the planets appear at the earth to move alternately forwards and backwards in the heavens, the retrograde motion not continuing so long as the direct motion. For a little time at the beginning and end of the retrogradation, the planet appears to have no motion. This arises when the relative MOTION of the planet is really towards the earth. The planet's velocity may always be decomposed into two, one in the direction of the earth's motion, or its opposite, the other towards or from the earth. When it happens that the former motion is not only parallel to that of the earth, but equal to it, the planet cannot change its place in the heavens, but all its apparent motion is the remaining motion, directly to or from the earth. If the planet were so near that we could readily see alterations of its distance, we should say it was directly approaching or receding: but as we cannot see this phenomenon, we pronounce it stationary, and for some nights we lose the distinction between it and the fixed stars. [TROCHOIDAL CURVES.]

STATIONARY. This term requires introduction into mechanics in a manner corrective of the mistakes which have sometimes been made. One of these is pointed out in STABLE AND UNSTABLE. Instead of saying that a system acted on by its weight is in equilibrium only when the centre of gravity is highest or lowest, it is there pointed out that all that is necessary is that the motion which the centre tends to take should be horizontal: or that the centre should be *stationary* as to ascent or descent, for the moment. Again, there is what is called the *principle of least action* [VIRTUAL VELOCITIES], which the mathematician will recognise in the theorem that the motion of a system is always such that $\Sigma m \int v\, ds$ is a minimum. Now all that is proved is that in the motion of a system, in the language of the calculus of VARIATIONS, $\delta \Sigma m \int v\, ds$ is $= 0$. Now all that this requires is that $\Sigma m \int v\, ds$ should be *stationary*; or that if a path infinitely near the path of motion should be chosen, $\Sigma m \int v\, ds$, calculated for the new path, should differ from the same calculated for the old path, by a quantity of an order inferior to those on which the difference of the paths depends. Sir W. Hamilton proposes to call this the principle of *stationary* action, instead of that of least action; the action of a particle whose mass is m moving over an arc s being a name given to $m \int v\, ds$, taken from one end of the arc to the other, where v represents the velocity.

STATISTICS is that department of political science which is concerned in collecting and arranging facts illustrative of the condition and resources of a state. To reason upon such facts and to draw conclusions from them is not within the province of statistics; but is the business of the statesman and of the political economist. In order to exemplify the precise character and limits of statistics, the Statistical Society of London have aptly chosen for their emblem a wheat-sheaf, with the motto "aliis exterendum."

That it is necessary for a government, in order to govern well, to acquire information upon matters affecting the condition and interests of the people, is obvious. Indeed the civilisation of a country may almost be measured by the completeness of its statistics; for where valuable statistical records of ancient date are found concerning a country not yet advanced in civilisation, which would appear to contradict this position, we owe them to sovereigns or governments of uncommon vigour and sagacity. However rude the government of a country may be, it cannot attempt to make laws without having acquired the means of forming a judgment, however imperfect, as to the matters brought under its consideration. In this sense statistics may be said to be coeval with legislation; but as the latter has rarely been conducted upon any fixed principles, or partaken of the character of science, in the earlier ages of the world, we must attribute to statistics, as a department of political science, a much later origin. It is chiefly to the rise of political economy that we are indebted for the cultivation of statistics. The principles of that science, which are directly concerned about the prosperity and happiness of mankind, were not reduced to any system until the middle of the last century; since that time, political economy has been cultivated as an inductive science. The correctness of preconceived theories has been tested by the observation and analysis of facts; and new principles have been discovered and established by the same means. A limited knowledge of facts had previously been an obstacle to the progress of political economy; and on the other hand the neglect of that science caused indifference to statistical inquiries.

This connection between political theories and statistics, while it has led to the collection of many data which would not otherwise have been obtained, has too often introduced a partial and deceptive statement of facts, in order to support preconceived opinions. This is sometimes unjustly objected to statistics, as if it were a defect peculiar to them. That facilities for deception are afforded by statistics cannot be denied; but fallacies of this kind, like all others, are open to scrutiny and exposure. Reliance need not be placed upon statements of facts nor on numbers, unless supported by evidence; and inferences from them should only be admitted according to the rules by which all sound reasoning is governed. Fallacies are difficult to detect in proportion to the ingenuity of the sophist and the ignorance or inexpertness of his opponents; but in political matters, opposite theories and opinions are maintained with equal ability, and facts and arguments are investigated with so much jealousy, that, in the end, truth can hardly fail to be established. Neither does any suspicion of partiality attach to such facts as are collected by a government without reference to particular theories. Until some one has shown the value of noting a certain class of facts with a view to his own inquiries, no pains are taken to obtain information of that nature from the best sources; but as soon as the importance of seeking any data is acknowledged, the collection of them becomes the business of impartial persons. The statist must be acquainted with the purposes to which the facts collected and arranged by him are likely to be applied, in order that the proper distinctions and details may be noted in such a manner as to give the fullest means of analysis and inference; but his services are greatest when he does not labour in support of a theory.

It thus becomes the duty of a government to apply all the means in its power in aid of statistics, not only for the administration of the affairs of state, but also for the furtherance of political science, and for general information. Abundance and accuracy must be the object of a government in collecting statistical facts.

We would lay much stress upon the collection of facts by the highest authority of the state, because the classes of facts most important in political inquiries can scarcely ever be searched out by other persons, who have not access to the offices of government, and who are without authority to demand information; while the government has ample means at its disposal, and can, without difficulty, and in the ordinary course of executive business, obtain statistical information of the highest value. In this and many other countries the respective governments are applying themselves earnestly to statistical investigations. In England a statistical department has been established at the Board of Trade to collect and arrange all the documents of a statistical nature that can be obtained through any department or agency of government. The admirably organised departments of the French government have abundance of statistical materials systematically collected, which they never fail to arrange in a very lucid manner, and to analyse with much ability. Great credit is due to the Belgian government for the diligence with which its several departments have engaged in statistics under the superintendence of a central statistical commission. Austria, Prussia, and other European governments, have also more or less complete and comprehensive statistical departments.

But while governments are thus engaged, there is ample room for the labours of individuals. Local statistics of all kinds are open to them. The books and records of public institutions, facts relating to particular trades, to the moral and social state of different classes of society, and other matters apparently of local interest only, often present results as important as those derived from inquiries on a more extended scale. Good service also may often be done by a judicious selection and comparison of matters not brought together in official statements, with a view to the illustration of principles of science or experiments in legislation, and by suggestions and criticism, which may direct the attention of government to particular branches of inquiry, to improvements in the mode of carrying them on, or in the form in which they are published.

It would be useless to attempt an enumeration of the various matters that are included in the province of statistics, but for the more convenient consideration of the subject we may indicate its division into—1, Historical statistics, or facts illustrative of the former condition of a state; 2, Statistics of population; 3, of revenue; 4, of trade, commerce, and navigation; 5, of the moral, social, and physical condition of the people.

The article CENSUS will serve as an example of the use to which such materials may be applied, and the parliamentary returns of the Board of Trade and the criminal and legal statistics now published annually furnish other examples.

STATUARY, STATUE. [SCULPTURE.]

STATUTE. Bills which have passed through the houses of Lords and Commons and received the royal assent become acts of parliament, and are sometimes spoken of collectively as forming the body of "statutes of the realm." In a more restricted application of the word, private acts are excluded, and even public acts, when their purpose is temporary. The meaning of the word is even more restricted when the measures of the early parliaments are in question, for many acts received the royal assent, and are found on the Rolls of Parliament, which are not accounted statutes.

The Statutes of the realm, properly so called, were at a very remote period written in books apart from the other constitutions and charters of the monarchy, and received by the courts as of equal authority with the ancient customs of the realm.

Three volumes, in the custody of the Master of the Rolls, contain the body of those enactments which are called "statutes." One contains those passed before the beginning of the reign of Edward III.; and the other two, those from 1 Edward III. to 7 Henry VIII., all very fairly written. These books are not considered in the light of authorised enrolments of the statutes. For the authentic and authoritative copies, if any question arise, recourse must be had (1) to what are called the Statute Rolls, which are six rolls containing the statutes from 6 Edward I. to 8 Edward IV., except from 8 to 25 Henry VI.; (2) to the enrolments of acts of parliaments which are preserved in the Rolls chapel from 1 Richard III.; (3) to exemplifications and transcripts with writs annexed, signifying that they were transmitted by authority to certain courts or other parties, who were required to take notice of them; (4) in those since 12 Henry VII., to the original acts in the parliament office; (5) the rolls and journals of parliament; (6) the close, patent, fine, and charter rolls; on which statutes are sometimes found.

With the parliament of the reign of Richard III. began the practice of printing, and in that manner publishing, the acts passed in each session. This followed very soon on the introduction of printing into England. Before that time it had been a frequent practice to transmit copies of the acts as passed to the sheriffs of the different shrievalties to be by them promulgated. The practice of printing the statutes has continued to the present time.

Before the first of Richard III., the aid of the press had been called in to give extended circulation to the older statutes. Before 1481 it is believed that an abridgment of the statutes was printed by Letton and Machlinia, which contains none later than 33 Henry VI., 1455. To the next year is assigned a collection, not abridged, from 1 Edward III. to 22 Edward IV. Next to these in point of antiquity is to be placed a collection printed by Pynson about 1497, who also, in 1508, printed what he entitled 'Antiqua Statuta,' containing Magna Charta, Charta de Foresta, the Statutes of Merton, Marlbridge, and Westminster primum and secundum. This was the first publication of those very early statutes.

In the reign of Henry VIII. the first English abridgment of the statutes was printed by Rastall; and during that reign and in the succeeding half century there were numerous impressions published of the old and recent statutes in the original Latin and French, or in English translations. Barker, about 1587, first used the title 'Statutes at Large.'

In 1618 two large collections of statutes ending in 7 James I., were published, called Rastall's and Pulton's. Pulton's collection was several times reprinted with additions.

In the 18th century an addition, in six folio volumes, was published by Mr. Serjeant Hawkins in 1735, containing the statutes to 7 George II. Cay's edition, in 1758, in the same number of volumes, contains the statutes to 30 George II. Continuations of these works were published as fresh statutes were passed; and another work in 4to, of the same kind, was begun in 1762, well known by the designation of Ruffhead's 'Statutes at Large.' Pickering's edition is in 8vo., and ends with 1 George III.

None of these collections, however, had ever been published by authority of the state. This led a committee of the House of Commons, who, in 1800, were appointed to inquire into the state of the Public Records, to recommend, among other things, that "a complete and authoritative edition of all the statutes should be published." And finally, between the years 1810 and 1824, the Record Commissioners appointed, in pursuance of this recommendation, produced a critical edition of the statutes (including the early public charters), ending with the close of the reign of Queen Anne. This is the *authentic* edition of the statutes. It is supplied with a valuable index, and forms ten folio volumes. In the introduction to that work there is a more particular account of the former editions of the statutes and of the means for making such a work as this complete.

The statutes passed in the Imperial Parliament of Great Britain are now printed by the queen's printers, and sold at fixed prices.

These "Statutes of the Realm" are generally divided into two classes—Public and Private; but they may more conveniently be distributed into three classes—Public General, Public Local, and Private. The two former only come within the term "laws," in the proper acceptation of the term. The private acts embody special privileges conferred on individuals, or the sanction of the legislature to private arrangements regarding property; and before they can be enforced, they must be pleaded before the courts of law, like contracts, or the titles of estates. The public local statutes, though published separately, and though the standing orders of the Houses of Parliament require that, on account of the private interests which they are often likely to affect, certain preliminary notices and other proceedings should take place before they are passed through their stages, are yet, in contemplation of law, in the same position as the public general statutes.

Formerly all the public statutes, local and general, were published together and numbered consecutively; but from the year 1798 downwards, the local acts have been separately enumerated. From the number of railway and other joint-stock schemes, this branch of legislation increased so rapidly a few years ago, that it became necessary to simplify and abbreviate it. Steps were taken to accomplish this end by passing what are known as Consolidation Acts, such as the Land Clauses Consolidation Act, the Railway Clauses Consolidation Act, &c., &c., a distinct series being passed applicable to Scotland; but there is yet room for further legislation in the same direction.

STATUTE (SCOTLAND). It would be difficult to explain the character of the older legislation of Scotland, the method in which it was sanctioned, or the constitution of the bodies by which it was passed. All the light that probably is to be obtained on the early history of the statute-law has lately been embodied by Mr. Innes, in his preface to the edition of the 'Scottish Statutes and Old Laws,' published by the Record Commission. "Whatever," he says, "may be the case in other countries, it is not easy in Scotland to distinguish the ancient legislative court or council of the sovereign from that which discharged the duty of counselling the king in judicial proceedings. The early lawgivers, indeed, enacted statutes by the advice of the 'bishops, earls, thanes, and whole community,' or 'through the common counsel of the Kynryk;' but during the reigns previous to Alexander III. we find the king also deciding causes in a similar assembly of magnates; while laws of the greatest importance, and affecting the interest of whole classes of the community, bear to be enacted by the king and 'his judges.'" It is probable that the practice of the assembly, legislative or judicial, of the principal barons, though irregular, was in general an imitation of the parliament of England.

Before the war of independence, the lands of the southern districts of Scotland had been in a great measure partitioned among Norman adventurers, some of whom owed a double allegiance to the crowns both of England and Scotland; and it was natural that they should bring with them the practices and opinions of the country with which they were earliest connected. A large proportion of the lowland population of Scotland were at the same time Saxon refugees from England. So early as the reign of David I. (1125) we begin to find that the municipal corporations had a voice in the ratification of the laws. "The parliament," says Mr. Innes, "assembled by John Balliol at Scone, on the 9th of February, 1292, was probably the first of the national councils of Scotland which bore that name in the country at the time, although later historians have bestowed it freely on all assemblies of a legislative character. We have no reason to believe that any change in its constitution occasioned the adoption of the new term, which soon became in Scotland, as in England, the received designation of the great legislative council solemnly assembled. It was not till a few years later, on occasion of negotiating an alliance with France, that Balliol, probably at the desire of the French king, procured the treaty to be ratified, not only by the prelates, earls, and barons, but by certain of the burghs of his kingdom. That treaty was finally ratified at Dunfermline on the 23rd day of February, 1295; and the seals of six burghs were then affixed to the deed, along with those of four bishops, four monasteries, four earls, and eleven barons. Notwithstanding this very formal ratification, however, it may be doubted, both from the peculiar phraseology of the deed itself, and from the silence of historians as to any meeting of a parliamentary nature in which it could have been voted, whether the parties stated as consenting, and especially whether representatives of those six burghs, were actually present as in a national assembly or parliament."

The acts which were thus sanctioned—sometimes, perhaps, by the separate adhesion of the principal interests of the country, sometimes in assemblies—were of a mixed character. Some were judgments in particular disputes, accompanied probably by the announcement of a principle on which such questions should thenceforth be decided; others were acts of executive authority; and others might be regulations having the character of fixed and general laws. When these proceedings related to matters of private right, the recording instrument would be put into the hands of the party interested. "When the proceedings of the national council," says the authority already cited, "related to matters of a more public nature, such as negotiations with foreign states, its earliest records were probably of a similar kind, and consisted of nothing more than the indentures or other diplomacy which embodied the results of its deliberations. Perhaps the earliest instances of this kind that now remain are those important deeds of the reign of Alexander III., when, however, a more artifical system must have been beginning to prevail. It would be still more interesting to ascertain the modes in which the more general ordinances and laws of the realm were enacted and recorded; but on this head the loss of every original document has left us entirely to conjecture. Judging, however, from the mutilated and imperfect transcripts of a later age, and from the analogy of the other states of Europe, it would appear that the more important and general statutes were framed into short capitulars, and ingrossed into a writ, addressed, in the name of the king, to the chief ministers of the law in the different districts of the kingdom, requiring the publication and observance of them. The laws of the burghs, the assizes of David I. and of William, and the statutes of Alexander II., as found in the old manuscript compilations of lawyers, seem to be the fragments of various capitulars of this kind." The assizes of David I., 'Assisé Regis David,' are reported to be the oldest fragments of legislation in Scotland, and are partly, but not entirely, traceable to so early a period as the reign of the king with whose name they are associated. The burgal laws, 'Leges Quatuor Burgorum,' constitute the oldest systematic collection of laws. They too may be referred to the reign of David; and though historians give him the credit of having planned the whole system of the municipal corporations, it is more likely that this code of laws embodies the privileges and restrictions which had gradually come into existence with the growing influence of the burghs. The coincidence between these early vestiges of Scottish legislation and the old law of England is remarkable. Both in the assize and in the burgh laws technical phraseology is frequently used, which still belongs to the law and practice of England, but has long been disused in Scotland. Indeed, it is very clear that before the attempt of Edward I. there was much harmony in tone and spirit between the two nations, and that Scotland generally followed or accompanied England in her constitutional progress. There is a still more remarkable coincidence of legislation in the celebrated 'Regiam Majestatem,' or general code of the old laws of Scotland. It was, like the fragments mentioned above, attributed to David I., who had obtained the character of the Justinian of Scotland; but it is undoubtedly of later date. In the 16th and 17th centuries it was very popular, as an undoubted early national code; but it was subsequently discovered to have many features in common with the compilation 'De Legibus et Consuetudinibus Angliæ,' attributed to Ranulph de Glanvil, justiciar of England; and then it acquired the evil reputation of being a code prepared by Edward I., for the purpose of subjecting Scotland to the law of England.

The 'Regiam Majestatem,' so named from the words with which it commences, is, along with the burgh laws, and other vestiges of early legislation, printed in the first volume of the edition of the Scottish statutes issued by the Record Commission. None of the contents of this first volume, however, come within the description of the accepted statute law of Scotland. In 1566 a commission was issued for the collection and publication of the statute law, and they speedily published a series of statutes reaching from 1424 to 1564. It is at the former date that the statute law, properly speaking, commences, and it proceeds thence in a regular series to the Union with England. The Scottish acts are referred to by the date of the parliament in which they are passed, and their numerical order; as, "The Act 1424, c. 25;" "The Act 1661, c. 16." These early statutes are brief and sententious, and were admired by Bacon for "their excellent brevity."

From the date of the accession of Bruce, after the war with England, the Scots long entertained a feeling of national jealousy and enmity towards England; and though some of the kings introduced southern practices, we do not find that steady imitation and adoption of the constitutional movements of the English parliament which characterise the earlier period, but rather an isolated creation of, and adherence to, national peculiarities. The subsequent creation of the Court of Session, in imitation of foreign tribunals, to administer justice, according to the rules of the Civil Law, has eradicated nearly all the traces of similarity in laws and procedure which formerly existed between the judicial systems of Scotland and England.

Of the Statutes of the Scottish parliament, those only are now law which are said to be *in viridi observantiâ*. By this principle the statute law has silently adapted itself to the character of the times; and, though not formally repealed, the barbarous laws of periods of bigotry or violence have ceased to be enforceable. Since the Union of 1707, it has been considered, in conformity with the English doctrine, that an act passed by the British parliament must be held as law, and judicially enforceable, until it is repealed.

The law of Scotland, the judicial and executive system, and the ecclesiastical polity, being quite distinct from the corresponding institutions of England, many statutes are from time to time passed by the British legislature solely applicable to Scotland, prepared by persons professionally acquainted with the institutions of that part of the empire. The revenue laws of Scotland were formerly distinct; but now, with few exceptions, one system embodied in one series of acts applies to the United Kingdom. In matters of national policy, and frequently in the criminal law and in legislation for internal economy, acts are made applicable both to England and Scotland at the same time.

STATUTE (IRELAND). In Ireland, the method by which the early irregular convocations, called parliaments, passed their acts, appears to have been a close imitation of the English practice. The authenticated printed statutes begin in the year 1310, 3 Edw. II. After five short acts of this parliament there is a hiatus until the year 1429, although it is known in history that repeated parliaments were held in the interval. Many of these statutes are characteristic indications of the state of the country, and throw light on the domination of the English over the natives—for example, the 25 Hen. VI. c. 4, "An Act, that he that will be taken for an Englishman, shall not use a Beard upon his upper Lip alone; the Offender shall be taken as an Irish Enemy:" 28 Hen. VI. c. 3, "An Act, that it shall be lawful for every Liegeman to kill or take notorious Thieves, and Thieves found robbing, spoiling, or breaking Houses, or taken with the manner:" and in later times (the 7 Will. III. c. 21), "An Act for the better suppressing Tories, Robbers, and Rapparees; and for preventing Robberies, Burglaries, and other heinous Crimes." The Statute of Drogheda, commonly called Poyning's Law, passed in 1495 (10 Hen. VII.), had a marked influence on the later legislation and constitutional history of Ireland; as by it, all the acts then or late passed in England, "concerning or belonging to the common and public weal of the same," should be law in Ireland. It further provided that no measure should be proposed for the adoption of parliament until it had first received the royal assent in England. It is believed that this badge of servitude prevented the passing of many exterminating acts, which, in times of anarchy, discord, or tyranny, the Irish ministry, and their partisan-parliaments, would have readily passed. This act was repealed, and the independence of the Irish legislature restored by the measure of 1783. At the Union, in 1800, the Irish Parliament was merged in that of Great Britain and Ireland.

STATUTE OF FRAUDS. This name is applicable to any statute the object of which is to prevent fraud, but it is particularly applicable to the 29 Car. II. c. 3, which is entitled the "Statute of Frauds and Perjuries." One object of the statute was to prevent disputes and frauds by requiring in many cases written evidence of an agreement. Before the passing of this statute many conveyances of land were made without any writing as evidence of the conveyance. An estate in fee-simple could be conveyed by livery of seisin, accompanied with proper words, and a use could also be declared by parol. No writing was necessary to convey any estate in possession, for such estate is technically said to lie in livery; but a reversion could only be conveyed by deed. The Statute of Frauds declared that all leases, estates, and interests of freehold or terms of years or any uncertain interest in any lands or hereditaments, made by livery and seisin only, or by parol, and not put in writing and signed by the parties, &c., shall have the force of leases or estates at will only. But leases for not more than three years, whereon the rent reserved shall be two-thirds of the full improved value of the thing demised, are excepted by the statute. Further, no lease, estates, or interest either of freehold or terms of years, or any uncertain interest, not being copyhold or customary interest, shall be assigned, granted, or surrendered except by deed or note in writing. Another section of the statute provides that all declarations or creations of trust or confidences of any land, tenements, or hereditaments shall be manifested and proved by some writing signed by the party who is by law enabled to declare such trust, or by his last will in writing, or they shall be void. The 5th section of this statute declared that all devises of lands or tenements, as more particularly described in this section, should be in writing and signed in the manner here prescribed by three or four credible witnesses; and the 6th section related to the revocation of a devise in writing of lands or tenements. Both these sections are repealed by the 1 Vict. c. 26, which makes alterations in other provisions also of the Statute of Frauds.

There are several other important provisions in this statute, which may be omitted here. The purpose of the statute is to prevent fraud by requiring the evidence of writing, which is a better kind of evidence than men's memory. Its enactments have been usefully amended by the Mercantile Law Amendment Act, 1856, especially with reference to guarantees.

STATUTE MERCHANT. [Acton Burnel, Statute of.]

STATUTE STAPLE. [Staple.]

STATUTES OF LIMITATION. There appear to have been no times limited by the common law within which actions might be brought; for though it is said by Bracton (lib. 2, fol. 228), that, "omnes actiones in mundo infra certa tempora limitationem habent;" yet with the exception of the period of a year and a day, mentioned by Spelman ('Gloss.', 32), as fixed by the ancient law for the heir of a tenant to claim after the death of his ancestor, and for the tenant to make his claim upon a disseisor, all the limitations of actions in the English law have been established by statute. Certain remarkable periods were first fixed upon, within which the cause of action must have arisen. Thus in the time of Henry III., the limitations in a writ of right, which was then from the time of Henry I., was by the Statute of Merton, c. 8, reduced to the time of Henry II.; and by the Statute of Westminster, 1, c. 8, the period within which writs of right might be sued out was brought down to the time of Richard I. (Co. Lit., 114 b.)

Since the 4 Hen. VII., c. 24, which limited the time within which persons might make their claim to land of which a fine had been levied with proclamations, various statutes have been passed for the purpose of limiting the time within which actions and suits relating to real property may be commenced. The 21 Jac. I., c. 16, enacted generally that no person should make entry into any lands, but within twenty years next after his right of entry accrued.

By the 9 Geo. III. c. 16, the right of the crown to sue or implead for any manors, lands, or other hereditaments (except liberties or franchises) was limited to sixty years. Before this act, the rule that *nullum tempus occurrit regi* was universal. It still prevails as a maxim where not abridged by statute.

The next statute upon this subject is the 3 & 4 Will. IV. c. 27, by which great changes were made in the remedies for trying the rights to real property, and which embodies the greater part of the present law of limitations relating thereto.

No entry or distress can be made or action brought to recover any land or rent, but within twenty years after the right has accrued to the claimant, or some person through whom he claims.

But persons under the disability of infancy, coverture, idiotcy, lunacy, unsoundness of mind, or absence beyond seas, or persons claiming under them, notwithstanding the period of twenty years shall have expired, are to be allowed ten years after the person to whom the right first accrued has ceased to be under any disability or has died. Forty years is, however, a complete bar.

No part of Great Britain and Ireland, nor the adjacent islands, is to be deemed beyond seas, within the meaning of this act.

A mortgagee to whom a payment of principal or interest has been made, or an acknowledgment in writing has been given, has twenty years from the time of such payment or acknowledgment. (7 Will. IV. and 1 Vict. c. 28.)

Arrears of dower, or damages for such arrears, are not recoverable by any action or suit beyond six years before the commencement of the action or suit. Before the act, there was no limitation either at law or in equity to a claim for arrears of dower during the life of the heir. No arrears of rent or of interest in respect of any money charged in any manner on land or rent, or any damages in respect of such arrear of rent or interest, can be recovered but within six years next after the same respectively became due, or next after an acknowledgment in writing given to the person entitled thereto or his agent, signed by the person by whom the same was payable, or his agent.

The rents here dealt with are rents charged upon land only, to which the former statutes did not apply, and not conventional rents, the limitations as to which are provided for by the 21 Jac. c. 16, s. 3, and the 3 & 4 Will. IV. c. 42.

Limitations as to tithes and other ecclesiastical property are now regulated by 2 & 3 Will. IV. c. 100, and 3 & 4 Will. IV. c. 27.

As to advowsons, the 3 & 4 Will. IV. c. 27, s. 30, enacts that no *Quare impedit* or other action is to be brought after the expiration of the period during which three clerks in succession shall have held the same, all of whom obtained possession adversely to the right of the person claiming, or of the person through whom he claims, if the times of such incumbencies together shall amount to sixty years, and if not, then after such further period as with the times of such incumbencies shall make up the period of sixty years.

Limitations as to other incorporeal rights are now mainly regulated by 2 & 3 Will. IV. c. 71. [Prescription.]

The limitation in actions of assault and battery, is, by 21 Jac. I. c. 16, s. 3, four years after the cause of action arises.

Actions of slander must, by the same statute, be commenced within two years next after the words spoken.

The limitation applicable to actions arising upon simple contract, and actions founded in wrong, is, by 21 Jac. I. c. 16, s. 3, six years next after the cause of action arises.

Formerly there was no limitation applicable to a suit for a legacy, though in some cases presumption of payment was admitted. The 3 & 4 Will. IV. c. 27, s. 40, is applicable to all legacies, whether charged on real estate or not.

The limitation on actions arising upon specialty is, by 3 & 4 Will. IV. c. 42, twenty years.

Actions of debt for rent upon an indenture of demise, actions of covenant or debt upon bond or other specialty, and actions of debt or *scire facias* upon recognisance must therefore be commenced and sued within twenty years after the cause of such actions or suits arises. But if any acknowledgment has been made, either by writing signed by the party liable, by part payment, or part satisfaction, on account of any principal or interest then due thereon, the person entitled may bring his action for the money remaining unpaid, and so acknowledged to be due, within twenty years after such acknowledgment or part payment, and in case of the plaintiff being under disability, within twenty years of the removal of such disability.

The limitations of actions on penal statutes is, by 31 Eliz. c. 5, s. 5 (which act repeals a previous one, the 7 Hen. VIII. c. 3, upon the same subject), two years after the commission of the offence, if the suit be by the crown; and one year after the commission of the offence if by a private prosecutor.

A prosecution by the party grieved was not within the statute; but now, by the 3 & 4 Will. IV. c. 42, s. 3, all actions for penalties, damages, or sums of money given to the party grieved by any statute now or hereafter to be in force must be brought within two years after the cause of such actions or suits.

By the 24 Geo. II. c. 44, s. 1, actions against justices of the peace and constables or others acting in obedience to their warrants are limited to six calendar months.

There is no time limited by any statute for indictments for felonies and other misdemeanors when there is no forfeiture to the queen or to the prosecutor.

A charity is never considered in equity as absolutely barred by the statutes, or by any rule of limitation analogous to them; but the court takes notice of a long adverse possession in considering the effect and construction of instruments under which claims are set up on its behalf.

The statutes of limitation must in general be pleaded positively by the defendant in any action at law, who wishes to take advantage of them, and it has been held in equity that unless the defendant claims the benefit of the statutes by plea or answer, he cannot insist upon them in bar of the plaintiff's demand.

STEALING. [Larceny.]

STEAM AND STEAM-ENGINE. *Steam* is the gas or vapour given off by a liquid, when its temperature is raised to such a degree as to cause it to pass into a state of ebullition; but as the vapour of water so given off is the one most commonly applied in the mechanical arts, attention will be called principally to that particular kind of steam in the ensuing notice.

Steam or vapour in its natural state, like all gases, is transparent and colourless; its visibility in air being caused by its partial condensation, which gives rise to the formation of small vesicles of water, enclosing transparent steam, of such a nature as to refract and absorb light. It seems that the phenomenon of the generation of steam is affected by the following general laws, namely: 1st, that the temperature of the ebullition of a liquid is the same at all times, under the same pressure and in a vessel of the same substance: 2nd, that the temperature of the liquid remains constant during the whole period of the ebullition, provided the pressure remain the same, and if a greater quantity of heat be communicated to the vessel containing the liquid at one stage of the process than at another, the only effect will be that a greater quantity of steam will be evolved: the temperature of the liquid will not be raised: 3rd, that the volume of the steam will be much greater than that of the liquid furnishing it, and that the volume of the vapour of water, for instance, will be about 1700 times greater than that of the water itself. The temperatures at which particular substances pass into steam are very different, it may be added; thus whilst water boils at 212°, ether boils at 98·6°; concentrated sulphuric acid, at 617°; mercury, at 680°; sulphur, at 752°, &c. Even the most refractory metals when properly treated can be made to pass into the state of vapour, and there are others which pass into the gaseous state without passing through the liquid form, as for instance camphor, arsenic, iodine, &c., under which circumstances they are said to *sublime ;* whilst liquids occasionally pass into the state of vapour at temperatures below those required for ebullition, and they are then said to *evaporate.* Water evaporates at all temperatures; ice, and snow, sublime in dry winds.

The law with respect to ebullition ascertained by Dalton, namely, "that the elastic force of the vapour given out during the process is equal to the exterior pressure," allows us to calculate the former from the temperature at which ebullition takes place, if we possess tables showing the elastic force of steam at the different temperatures; and it is upon this principle that hypsometric observations with respect to the altitudes of mountains are made, by ascertaining the boiling point of water in open vessels. Very great precautions are requisite in observations of this description, but with the aid of the hypsometric thermometer of M. Regnault, very useful checks upon the other modes of ascertaining altitudes may be obtained. Amongst other essential points to be taken into account in these observations the nature of the vase must not be neglected, for Gay-Lussac observed that water required a greater degree of heat to pass into a state of ebullition when it was boiled in a glass vase than when it was boiled in a metal one: and it is well known that when the vase is covered with a material with which water may have less cohesion than it has with the metal, the boiling point may be lowered. Thus, if the boiling point of water in a metal vase be at any place 212°, it would usually be 213°·96 in a glass vase; but if the glass be covered by a coating of shell lac, the boiling point would become about 211°·64. It also appears that the quantity of air diffused through the water has a considerable effect on the formation of steam; for unless there be air in dissolution, the cohesion of the particles of the water will oppose the disengagement of steam, excepting upon the surface. Galy Cazalat found indeed that, by excluding air from water exposed to heat, it was possible to raise the temperature to about 253°·4 without ebullition, but that at that temperature part of the water flashed into steam with a violent explosion. There are some curious facts connected with the spheroidal condition of water in contact with incandescent materials which are worthy of the attention of the physical philosopher; but as they have not hitherto led to any practical results, the reader is referred, for a view of the present state of our knowledge on this subject, to the works of Boutigny, Pouillet, Poggendorff, Perkins and Faraday.

The temperature of ebullition is not affected by the presence of substances in suspension in the liquid considered; but when those substances are in solution they produce a very distinct effect, and in the proportion that the new ingredient is more or less volatile than the liquid, will the boiling point be lowered or raised. Salts dissolved in water retard its ebullition, and they do so in an increasing ratio until the point of saturation has been reached, beyond which the boiling point remains constant; but it is to be remarked that the precise temperature of ebullition of a saline solution is not to be judged by the degree of heat that solution may temporarily attain; for it is possible to raise the temperature to a certain degree, but directly the salt begins to be precipitated the temperature may fall. Thus, a solution of the carbonate of potash was observed by Legrand to attain 284° without parting with that substance; but suddenly a great effervescence took place, and the temperature fell to 275°, accompanied by a copious deposition; after which the temperature remained constant. M. Legrand gave a table of the boiling points of the different saturated saline solutions, from which the following statement is copied; the temperatures are of course given in this table, and throughout this article, unless otherwise mentioned, on the Fahrenheit scale.

Salts.	Salt in 100 parts of water.	Temperature.	Salts.	Salt in 100 parts of water.	Temperature.
Chloride of sodium .	41·2	227·12°	Sal ammoniac . .	88·9	237·56°
,, potassium	59·4	226·94	Chloride of strontium	117·5	244·18
,, barium .	60·1	219·92	Carbonate of potash .	205·	275·0
Carbonate of soda . .	48·5	217·33	Nitrate of lime . .	362·	271·8
Nitrate of soda . .	224·8	249·8	Acetate of soda . .	209·	261·7
,, ammonia .	No limit	356·	,, potash .	798·2	336·2
Chloride of calcium .	325·0	355·1	Phosphate of soda .	112·6	234·7

The boiling point of water being 212°, that of concentrated nitric acid will be 186°·8; that of alcohol will be 174°·2; that of oil of turpentine will be 314°·6; and that of linseed oil 600°·8. Sea water, containing $\frac{1}{33}$ of its own weight of the chloride of sodium, boils at 213°·2 in the open air; if the proportion of salt be increased, the temperature of ebullition will increase also; thus, for $\frac{2}{33}$ of salt it becomes 214°·4; for $\frac{3}{33}$, it becomes 215·°5; for $\frac{4}{33}$, 216·°7; for $\frac{5}{33}$, 217·°9; for $\frac{6}{33}$, 219°; for $\frac{8}{33}$, 221°·4; for $\frac{10}{33}$, 223°·7; for $\frac{12}{33}$, or the point of saturation, 226°. It may be interesting to the practical reader here to state, that marine boilers are usually worked with proportions of salt equal to $\frac{2}{33}$ of the weight of the water; but that occasionally those proportions are raised as high as $\frac{4}{33}$ without much inconvenience.

For mechanical purposes, it is necessary that steam should exercise a pressure in excess of that of the atmosphere; and, upon Dalton's law above quoted, this additional pressure, or elastic force, can only be obtained by causing the water to boil under such conditions as shall bring to bear upon its surface an effort equivalent to the one the steam is desired to exercise. It is a matter of the greatest importance in the arts, then, to ascertain the temperature of the water which corresponds with steam of certain pressures, and numerous experiments have been made for this purpose. Messrs. Dulong and Arago, M. Regnault, and Macquorn Rankine, may be cited as the greatest authorities on the subject; and the reader who may desire to study this branch of physical science in detail is referred to their works, as also to those of Wollaston, Lavoisier, Laplace, Gay-Lussac, Petit, De Pambour, Lubbock, Mosely, &c. The tables drawn up by Messrs. Arago and Dulong of the elastic force of steam at the different temperatures observed during their experiments, or ascertained by calculation by means of a formula deduced from those experiments when the elastic force of the steam exceeded 392·8 lbs. on the superficial inch, are sufficiently accurate for practical purposes, though M. Regnault's later researches are more elaborately correct. Arago and Dulong's table is to be found in Daguin's 'Traité de Physique,' and elsewhere; the pressure being indicated in atmospheres of 14·7 lbs. on the superficial inch, and the temperatures are given on the centigrade scale. Macquorn Rankine, however, gives in his 'Treatise on the Steam Engine,' p. 564, a table, from which the following statement of the tension and the boiling points is extracted; the tension being given in pounds, the temperature of the water, producing the steam of that elastic force, in degrees of Fahrenheit's scale.

Table of temperature of water able to produce steam possessing the elastic force indicated, in lbs. avoirdupois per superficial inch :—

Temperature.	Force.	Volume of 1 lb. of steam in cubic feet.	Temperature.	Force.	Volume of 1 lb. of steam in cubic feet.
212°	14·70	26·36	329°	101·9	4·280
221	17·53	22·34	338	115·1	3·814
230	20·80	19·03	347	129·8	3·410
239	24·54	16·28	356	145·8	3·057
248	28·83	14·00	365	163·3	2·748
257	33·71	12·09	374	182·4	2·476
266	39·25	10·48	383	203·3	2·236
275	45·49	9·124	392	225·9	2·025
284	52·52	7·973	401	250·3	1·838
293	60·40	6·992	410	276·9	1·672
302	69·21	6·153	419	305·5	1·525
311	79·03	5·433	428	336·3	1·393
320	89·86	4·816			

In practice, the pressure of steam is reckoned without any reference to that of the atmosphere; or, in other words, it is only the pressure in excess of the atmospheric pressure which is noticed. Ordinary condensing engines, said to be working at from 16 to 40 lbs. pressure, would, according to the above table, work with steam of an elastic force of from 30·7 to 54·7 lbs.; high pressure engines, working at from 60 to 120 lbs. pressure, really work with steam of 74·7 and 134·7 lbs. of the table, and the temperature of the water would in both cases correspond with the higher degrees of elastic force. The laws connected with the relations between the temperature and pressure above stated are, moreover, sometimes applied practically in the arts as a precaution against danger from an accidental increase of pressure; for, on the continent, it is usual to place in a steam-boiler, intended to work under high pressure, plugs of mixed metals able to fuse at temperatures which would generate steam of a dangerous nature. When these plugs fuse, the water escapes, and consequently puts out the fire; they do not, however, dispense with safety-valves.

A great number of formulæ have been proposed for the purpose of calculating the relation between the elastic force of vapour and the temperature of the water producing it; such are the formulæ of Laplace, Ivory, Poisson, Lubbock, De Prony. The simplest of them is unquestionably the one given by Dr. Young, $F=(1+0{\cdot}0029t)^7$; or, as given by Arago and Dulong for the centigrade scale, $F=(1+07153t)^5$; and Regnault found that the results it gave corresponded very nearly with those obtained by actual observation, when the vapour was given off from water heated beyond 212°, but that below that temperature the results no longer agreed. Regnault adopted, therefore, another formula proposed by Biot, and discussed at length by that philosopher in his 'Traité de Physique,' 1816: but, as this formula contains no less than five constants, and the indications given by the simpler formula of Arago are admitted to be correct for all the pressures dealt with in practice, there can be little reason for adopting the former.

It is important, in calculations with respect to the use of steam as a motive power, to ascertain whether the latent heat of the steam remains the same at all temperatures; and M. Regnault has added to the other services he has rendered to science by going through a series of direct experiments for the purpose of verifying the laws of

Watt and of Southern upon this subject which had previously been received. Regnault found that at the ordinary atmospheric pressure it required 540 thermal units of the French scale to convert 1 gramme of water into steam (971,636 English thermal units to convert 1 pound avoirdupois); and thus far his experiments (recorded in the 'Mémoires de l'Académie des Sciences,' vol. xxi.) agreed with those of other observers. Watt, however, had laid down the law "that the quantity of heat necessary to vaporise a given weight of water was the same at every degree of the thermometer;" and Southern had stated "that the latent heat of vaporisation was the same under every degree of pressure;" De Pambour's observations appeared also to show that, up to a pressure of about 65 lbs. on the superficial inch, Watt's law was substantially correct. Regnault, on the contrary, found that Watt's law was not exact, and that Southern's was still more fallacious; for he found that when the temperature increased, the total heat also increased, but the latent heat diminished. The results of his experiments were given in the following formula, $\lambda = 606{\cdot}5 + 0{\cdot}305t$; in which λ is the total heat (on the centigrade scale), and t the temperature of the steam; the coefficient 606·5 being the value assigned by him as the latent heat of vapour at 0°, and 0·305 the specific heat of steam. Regnault ascertained at the same time that between the limits of 0° and 392° there was hardly any difference in the specific heat of water, so that there was no occasion to take that difference into account. In the Mémoire wherein these observations are recorded a table is inserted, showing the tensions, and the total heat of the vapour given off at temperatures increasing by equal increments of 10 degrees centigrade, between 0° and 230°. The table in question is also given in Daguin's 'Traité de Physique,' t. i., part 2, p. 965. It may be as well to add that the laws of the latent heat of steam are practically applied when buildings are heated by means of it; in these cases the heat absorbed, or rendered latent in one place, is distributed by the pipes which enable the steam to circulate over other parts of a building.

The following table of the densities of vapours is extracted from Daguin's work; it is based upon the experiments of MM. Gay-Lussac and Dumas, and the density of air is taken as unity.

Substances.	Density of vapours.	Point of ebullition.	Substances.	Density of vapours.	Point of ebullition.
		Centigrade.			Centigrade.
Water . . .	0·6235	100°	Sulphuric ether .	2·5860	36°
Hydrocyanic acid .	0·9476	26·5	Sulphide of carbon .	2·6447	47
Alcohol . . .	1·6138	11	Essence of turpentine	5·0130	157
Hydrochloric ether .	2·219	36	Hydroiodic ether .	5·4749	65

Compared with water at its greatest degree of condensation, the density of steam at 212° Fahr. is exactly 1695 less than that of the water, or nearly 1700, as was before stated; or in fact, one volume of water yields nearly 1700 volumes of steam. This is worthy of remark; for the volumes of the oxygen and hydrogen, contained in a given volume of water, occupy under atmospheric pressure a space equal to 2500 times the volume of the latter. It has been suggested that the condensation which thus appears to have taken place during the combination of the permanent gases referred to, may be explained by some change in their electrical state; and it is well known that the evolution of steam, under high pressures, does give rise to electrical phenomena of a very remarkable but hitherto only partially studied description. Messrs. Armstrong, Faraday, Schafthoentl, and Becquerel have, indeed observed that when steam, charged with water in suspension, escapes in such a manner as to exercise friction against a substance opposed to its passage, a development of electricity takes place, and that generally the water or the vapour is positive, and the opposing substances negative. The form, the nature, and the temperature of the orifices affect the development of the electricity to a great extent, and especially does heat retard it; at the same time the amount of electrical action depends on the purity of the water, for a small quantity of salt or acid destroys the property, and a very small proportion of the essence of turpentine causes the nature of the electricity to change; the steam in this case becomes negative. Becquerel evidently attributes the development of the electricity, by the passage of steam under the circumstances recorded in the experiments of Mr. Armstrong, to the friction of the globules of water contained in the steam; but this interesting question has not yet been examined with sufficient accuracy to allow the formation of any absolute opinions on the subject.

Steam-Engine. In conformity with the plan of this Cyclopædia a general outline of the principles of the engine will be here given, the reader being referred to different articles connected with the subject, or to works written specifically on the steam-engine, for more detailed information.

The claim to the invention of the steam-engine has been made a subject of national contention; but the conclusion, arrived at from the discussions which this contention has originated, seems to be, that, in common with all other important applications of physical principles, no individual can lay claim to the invention. Whatever may have been the nature and date of its origin, it has been reared to its present gigantic stature by the fostering care of different countries, and, without detracting from or underrating the efforts of others, England may be justly proud of her share of the glory, a share readily conceded by our competitors.

Considering therefore dispute as unprofitable, and the discussion of dates of patents and improvements as uninteresting, we shall incorporate all that is requisite of the history of the engine with our account of it.

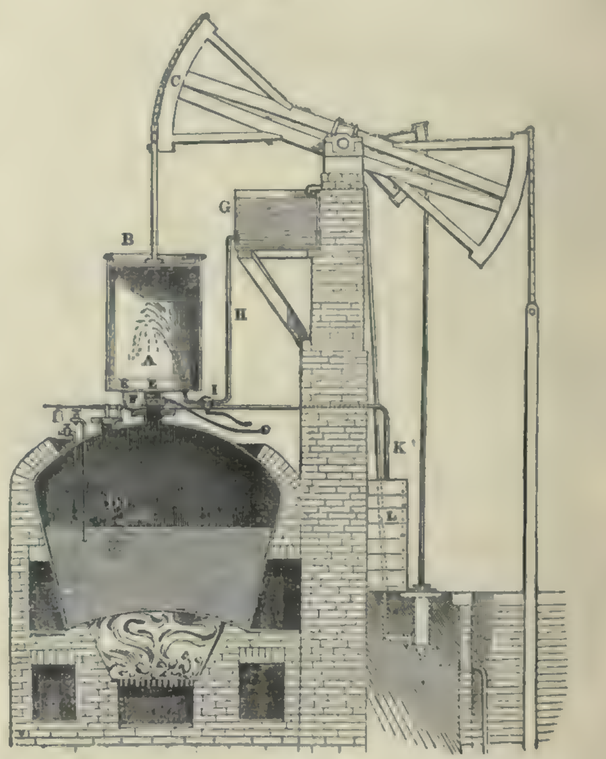
A steam-engine may be defined generally as an engine by which the forces arising from the properties of elasticity and of instantaneous condensation possessed by steam are transmitted to produce a continuous rotatory motion, either of a fly-wheel designed to constitute a reservoir of power for the purposes of driving machinery, or for any other uses that force may be put to.

Admitting this definition, the earlier steam-engines, as they are commonly called, those of the Marquess of Worcester (1663), and the improved forms contrived or suggested by others, and even Captain Savery's (1698), which was long employed in this country, were only *pumps* for raising water: a partial vacuum was formed in close vessels by the condensation of steam within them, the atmospheric pressure raised the water to a certain height; from whence it was forced higher by the elasticity of the steam admitted to act on its surface.

Passing over all these therefore as foreign to our subject, the first engine which it is necessary to describe is that of Newcomen (1705); it constitutes the connecting link between the steam-pumps alluded to, and the modern engine, of which it contained the germ, and into which it was converted by the genius of Watt. [WATT, JAMES, in BIOG. DIV.]

In the subjoined diagram, A represents a *cylinder* open at the uppe end, fitted with a *piston* B, and rendered air-tight by having water on it to the depth of several inches: the *piston-rod* was suspended by a chain from the arched end of a *beam* C, turning on an axle, and having a pump-rod at its other extremity, loaded so as to counterpoise the weight of the piston, and to raise it to the top of the cylinder. This cylinder was placed over the *boiler* D with which it communicated by a steam-pipe E, furnished with a cock F to open or close the passage: G is a cistern fixed above the cylinder, to the bottom of which a pipe H passed, also provided with a cock I.

Fig. 1.



When the piston was depressed to the bottom of the cylinder, it drove out all the air before it, which escaped at the orifice of a pipe K into the water of a smaller cistern L: the cock F being next opened, the steam from the boiler filled the cylinder as the piston rose again from the action of the counterpoise; as soon as it arrived at the top, the cock F was closed and I opened, a jet of cold water from the cistern G rushed into the cylinder, condensing the steam, and thus forming a partial vacuum beneath the piston, the pressure of the air on its upper surface forced it downwards, and caused the pump at the other end of the beam to raise an equivalent weight of water to a height equal to that through which the piston moved: the injected water and condensed steam-water flowed off into the cistern L through K, as the air had previously done. The cock I was now closed, and F opened, and the action was repeated, and when this engine was first introduced, it was the duty of an attendant to open and shut these cocks alternately; but subsequently lever handles to open and shut the cocks were acted on by pins or cams, carried by a rod suspended from a beam; and the engine became self-acting. This improvement was rudely made in the first instance by a boy named Potter, for the purpose of saving himself trouble; it was subsequently perfected by an engineer named Beighton in 1718.

Newcomen's engine was successively improved upon by Smeaton, Brindley, and other engineers, previous to Watt's time, and from its intrinsic merits it remained in general use under the appropriate name of the "atmospheric engine" during the greater part of the last century, but was only used for pumping water.

The first and most important of Watt's improvements on the engine consisted in effecting the condensation in a separate vessel, termed the *condenser*, which communicated with the cylinder. This condenser being filled with steam from the boiler at the same time with the cylinder, the jet of cold water, admitted into the former only, effected the condensation of the whole volume of steam, both of that in the cylinder as well as of that in the condenser, in conformity with the well-known principle in physics, that an action originated in any part of a homogeneous fluid is almost instantaneously communicated throughout its mass.

To effect still further the object of this separate condensation, Watt placed his condenser in a cistern, the temperature of which was kept constant by a fresh supply of cold water, brought from a well by a pump, to be presently mentioned; for otherwise, the heat given out by the condensing steam would, by heating the vessel and the water surrounding it, have prevented the rapid or almost instantaneous condensation necessary to the efficient action of the engine.

To comprehend the necessity for a rapid condensation, it must be remembered that the effective power of the engine depends on the pressure on the piston minus any resistance it encounters and on the space through which it moves. If the steam could be *instantly* converted into water, and so entirely removed,* a perfect vacuum would be formed beneath the piston, in which case, there being no resistance from this source to overcome, a maximum of power would be obtained; but if the condensation be slow, or only partial, since the piston will begin to move the instant there is any inequality in the pressures exerted on its opposite surfaces, its motion will be retarded, or the power diminished, by the resistance to compression offered by the uncondensed steam; and although that resistance would tend to diminish as the condensation proceeded, yet the space occupied by the steam diminishing in consequence of the descent of the piston in nearly the same proportion, the resistance would be nearly constant through the whole of that descent.

On the other hand, to maintain the temperature of the cylinder as high as possible, Watt, at first, cased it in wood to retard the radiation, and subsequently surrounded it by a second iron cylinder, admitting steam from the boiler between the two. This casing, or "jacket," as it is termed, is not used in most modern engines made since Watt's time, for reasons which will hereafter appear; and the effects of radiation from the surface of the cylinder are now chiefly guarded against as much as possible by keeping that surface bright and smooth.

The second of Watt's improvements on Newcomen's engine consisted in closing the cylinder at top, the piston-rod being made to pass through a cylindrical neck in that top, termed a *stuffing-box*, from the passage being rendered steam-tight by a stuffing of tow saturated with grease, which by its lubrication diminished the additional friction resulting from this arrangement. The object of this alteration was to admit of the elastic force of the steam being employed to impel the piston downwards, instead of simple atmospheric pressure. For this purpose, the steam was admitted from the boiler above the piston at the same moment the condensation took place in the condenser; the steam-passage being made double for the purpose, so that the communication with the condenser could be cut off when that with the cylinder was opened, alternately. When the piston had descended to the bottom of the cylinder, the counterpoise at the pump-rod raised it again, as in Newcomen's engine; but to allow of this upward motion, it was necessary to remove the steam which was above the piston, and this was done by allowing it to pass under the piston, and into the condenser through a passage opened at the proper instant for this purpose. Such is the general principle of Mr. Watt's *single-acting* engine, which hence became a *steam-engine*, and was no longer an *atmospheric* one.

By a further improvement, the counterpoise at the pump-rod was done away with, which obviously had been so much added to the unproductive work of the engine, since this weight had to be raised in addition to that of the water. The upward stroke of the piston was now produced by admitting the steam *below* it, to act by its elasticity, as it had previously done *above* when causing the piston to descend: thus the engine became *double-acting*, and assumed that essential general principle which it has ever since maintained, although all the details of its construction have been improved upon by successive engineers.

The changes in the engine introduced by Watt created the necessity for two pumps, and commonly three, which are worked by rods attached to the beam: the first of these is the *hot-water* or *air pump*, intended to remove the air, condensed water, and steam from the condenser, in which they would otherwise accumulate, and finally stop the action; for this water cannot flow away into an open cistern, as it had done in Newcomen's engine, since by Watt's principle it is essential that the condenser should be as steam-tight and as perfectly closed as the cylinder, or else the steam could not exert a pressure greater than that of the atmosphere, as it is intended to do in order to increase the effective force of the engine. The second is a force-pump, required to return the water drawn from the condenser by the first back to the boiler, as will be hereafter explained; and the third, termed the *cold-water pump*, is that alluded to in a preceding paragraph as supplying the cold-water cistern which contains the condenser.

Having thus explained the general principle of the engine, some of the details of its construction must now be considered, and the piston [HYDRAULICS] may claim our first notice, both from its paramount importance and the practical difficulties to be overcome in its formation. In hydraulic machines, all vessels, pipes, valves, &c., must be made *water-tight*: in Bramah's pump, for example, the efficiency of the engine entirely depends on the accurate fitting of parts moving in contact, which must be perfectly water-tight, though subjected to a pressure of many hundred pounds on each square inch of surface;—the utmost perfection of skill in workmanship is requisite to ensure this object, and the difficulty is obviously considerably increased when steam or gases are the fluids to be dealt with. Now the piston of a steam-engine must be *steam-tight*, and yet move with a minimum of friction in the cylinder; and as this latter, from defective workmanship, can never be a perfectly true one, the cylindrical periphery of the piston must be so contrived as to be capable of adapting itself to every inequality in the surface against which it slides: this is effected in common pistons by their being made two inches or more less in diameter than the cylinder, leaving a projecting flange at the bottom, which, together with a top plate bolted to them, accurately fits the cylinder. Tow or soft rope, saturated with grease, is carefully wound round the cylindrical body of the piston, between the upper plate and lower flange; the former is then drawn up by screws, compressing the intervening packing till it perfectly fits the cylinder, and yet by its elasticity allows of its adapting itself to the inequalities in the surface. The first (*fig.* 2) of the annexed figures will explain the details of the construction of the ordinary piston.

Fig. 2.

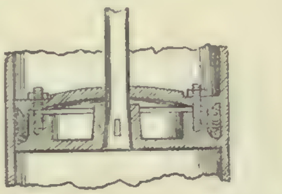


Fig. 3.

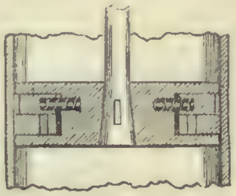

Fig. 4.

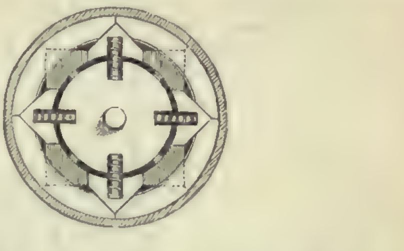

But as the friction of this common piston is necessarily very considerable, the better class of engines have usually what are called *metallic pistons*, of which there are different kinds, invented by Cartwright, Jessop, Barton, and others. The body of these pistons is metal, made in pieces or segments, acted on by springs radiating from a centre; so that while the friction is diminished by both surfaces being metallic, the piston, owing to its construction, can adapt itself to the irregularities of the cylinder. It is found in practice that these metallic pistons wear for a long time, and do not of course require the frequent repacking necessary to those with tow or hempen stuffing. *Figs.* 3 and 4 represent a plan and elevation of an improved form of Barton's piston, to explain the principle.

In Newcomen's engine the steam was admitted to the cylinder, and the communication again cut off by means of a cock of the common construction; but a more efficient contrivance is requisite when the steam is to be admitted alternately both above and below the piston, and to the condenser, as it is in engines since the introduction of

---

* One cubic inch of water occupies 1711 cubic inches of space, in the form of steam at 212°; consequently, the space occupied by the water after the condensation may be neglected in the computation.

Watt's improvements. This can be accomplished by a *four-passage cock*, originally invented by Leupold in 1720, and since improved by Bramah and others. The principle of a four-way cock will be understood by the annexed figure (*fig.* 5) of the plan of one employed by Messrs. Maudslay and Field in their small engines.

Fig. 5.

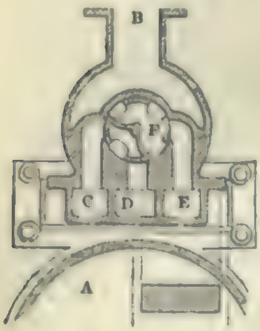

Fig. 6.

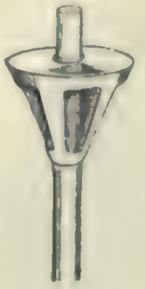
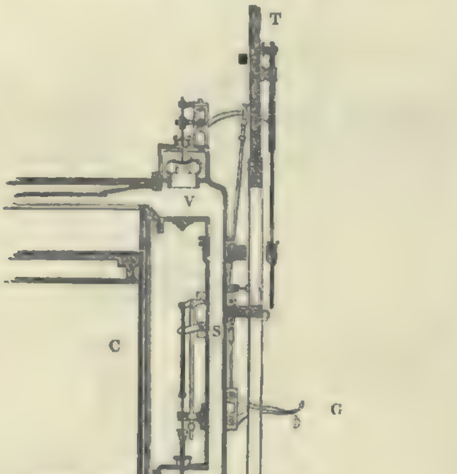


A is a portion of the cylinder; B, the steam-pipe; C, D, E, three passages, one communicating with the top, another with the bottom of the cylinder, and the third with the condenser; F is the four-passage cock, which, by turning alternately to the right and left, establishes a communication between one of the former with the latter passage. *Fig.* 6 represents the conical valve with its side apertures, and that at the top, by which the steam enters.

Watt employed flat conical valves for the purpose under consideration, which were raised or depressed by cranks acting on a guide-rod at right angles to the plane of the valve, which therefore did not turn on a hinge like the common *clack-valve* of a pump. In some of his engines the valves were raised or depressed by toothed sectors acting on a rack in the guide-rod, so that the valve might rise from its seat without altering the parallelism of its plane. Two such valves were mounted in one box, one above the other, the guide-rod of the lowest passing through that of the upper.

Fig. 7 shows the valves of this construction, of the large engine erected by Messrs. Maudslay for the Chelsea Water-Works. C, part of the cylinder; P, the piston; T, the "plug-tree;" G, the gearing handles, which are struck by the tappets on the plug-tree, and thus open and close the valves V; S, the steam-passage to the upper and lower parts of the cylinder; D, the passage to the condenser.

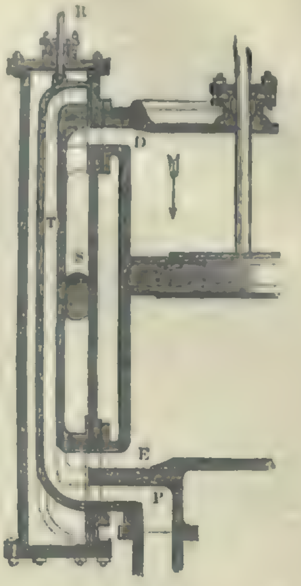
Fig. 7.



In most engines of the present day, however, the *slide-valve*, as it is termed, has superseded the use of the others, excepting in large pumping-engines: a perfectly flat surface slides on another, terminating the orifices which are to be opened and shut; such is the general principle, but the forms and arrangements are too numerous to be mentioned. *Fig.* 8 shows a part of the cylinder of an engine with *box-slide valves*, now much used.

S, the orifice of the steam-pipe; the steam passes to the upper part of the cylinder at D, the lower passage E being shut off in the position of the valve shown and shaded in the figure; the slide is moved by the rod R, and it is shown in its second position in dotted lines, in which position it will be seen that the steam can then enter *beneath* the piston, while the passage P to the condenser is in turn in communication with the upper part of the cylinder by means of the tube T of the slide.

Fig. 8.



The characteristic and most valuable part of this principle is this, of making part of the slide act as a pipe to connect the two parts of the cylinder alternately with the condenser. The steam, by pressing on the slide in the common form of slide, enormously increases the friction with the surface against which it acts, and also produces rapid wear of the parts; this defect is remedied in the box-slide and all others which possess this peculiarity.

Slide-valves were proposed by Murray, in 1799, but were abandoned, till improved workmanship allowed of their being more perfectly made; they have been successively improved in principle by Murdoch, Bramah, Millington, Maudslay, and Seward, the slides of the last-named being now much used in marine engines.

It has been mentioned that the alternate action of the valves in the atmospheric and Watt's engines was produced by pins, or *tappets*, adjusted on a rod called the *plug-tree*, suspended from the beam; as the plug-tree moved up and down with the beam, the tappets struck the ends of bent levers or cranks, which raised or depressed the valves in proper succession: some of these levers were so formed that the tappet by pressing against them might keep the valve closed during the greater part of the stroke* of the piston, and others required an intermediate shorter lever, or claw, to act on the valve-rod; so that the whole arrangement was inevitably complicated and cumbrous. But when the slide-valve superseded Watt's double conical valves, and the steam passages could be opened and closed by the motion of one rod only, connected with the slide, this motion could be readily produced by what is termed an *excentric*, which for this purpose usually consists of a circular plate of metal, keyed *excentrically* on the shaft of the fly-wheel, and working within a ring attached to the end of a frame intended to move a crank directly connected with the slide-rod at its other extremity. As the shaft revolves, the excentric plate imparts an alternating motion to the frame, which, transmitted by the crank, alternately raises and depresses the slide-rod. The principle of the excentric is one of the most valuable of those mechanical contrivances by means of which a continuous circular can be converted into an alternating rectilinear motion.

The "beam" so frequently alluded to, was obviously the readiest mode of connecting the alternating motion of the piston with the pump to be worked, in the atmospheric engine; and owing to the facilities it offers of working the plug-tree and the three pumps necessary in Watt's condensing engines, continued to form a part of the arrangement whether the engine were intended to pump a mine or to drive machinery. The beams of the first engines were made of two or more trees, bolted together to obtain the requisite rigidity, and further strengthened by a kind of truss, as is seen in the diagram of Newcomen's engine. But when the art of making heavy iron-castings was perfected, that metal was substituted for wood, to the manifest improvement of the engine in every respect. Watt also removed the cumbrous arched heads, which had been previously employed for the purpose of causing the piston-rod to move up and down in the same right line, though connected with the end of the beam, which necessarily described an arc of a circle, as turning on a fixed centre; this arrangement implied the use of a flexible chain, to suspend the piston, which might wind round, and unwind from, the arch, but a chain could not be used when the piston had to raise the beam, as it had to do in Watt's engine, instead of being raised by it, as in Newcomen's.

---

* The term *stroke* is technically used by engineers to express the whole motion of the piston from the top to the bottom of the cylinder and back again.

The object of these "arched heads" is attained in modern engines by a system of simple rods or levers, so combined that one point may move in a straight line nearly. There are a variety of combinations by which this may be effected, but that termed the "parallel motion," invented by Mr. Watt for the purpose, is the only one which need be here noticed, as being that most commonly used.

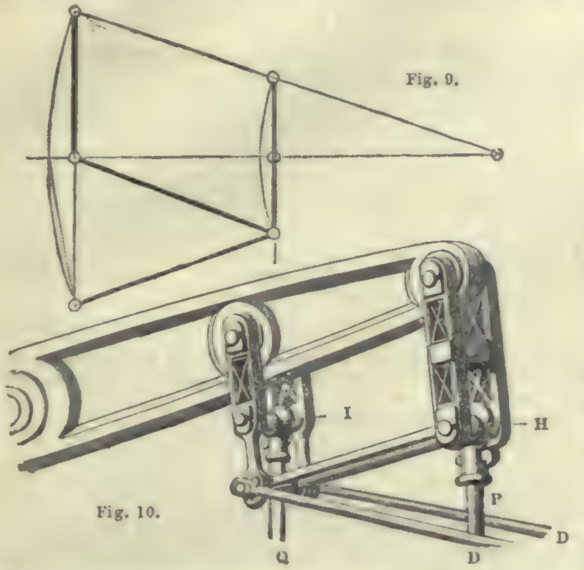


Fig. 9.

Fig. 10.

The geometrical principle of this motion is shown in *figs.* 9 and 10 as well as the whole arrangement when the piston is near the top of the cylinder: D D are rods fixed by one end to the frame supporting the beam, while the three other pair of levers being jointed together and to the beam, must obviously, in every position, form a parallelopipedon, whence the name is derived; P is the piston-rod attached to H; Q that of the hot-water pump connected with the parallel motion at I in the centre of that side.

When the engine is employed to drive machinery of any kind, a *fly-wheel* becomes a necessary adjunct to it. A fly-wheel is one in which the principal quantity of the matter is distributed in the periphery; when such a wheel revolves on an axis perpendicular to its plane, the greatest quantity of matter moving with a maximum velocity, the momentum of the whole is a maximum, while its inertia, if it be large, causes it to control, or equalise, the motion of the machinery through which it receives its own. It is the momentum of such a wheel which constitutes the disposable force available for the multifarious purposes to which machinery can be applied; so that in the case of the steam-engine, although the elasticity of steam is the original source of power, the immediate one by which the work is executed is the momentum of the fly-wheel.

It is consequently necessary to adapt some contrivance to the end of the beam, which shall convert the alternating circular motion of the latter into a continuous one of the fly-wheel; this is effected by the *rod* and *crank*, a piece of mechanism of such frequent occurrence that it is unnecessary to describe it; the treadle of a lathe is a familiar instance of its application, and for a similar purpose, that of connecting the alternate motion of the turner's foot with the continuous one of the wheel of the lathe; the principle of the treadle, or rod and crank, is in fact the only one by which an alternating can be converted into a continuous circular motion; it must therefore be employed, notwithstanding the variation in the power transmitted by means of it, consequent on that of the angle formed by the rod and crank with each other. Thus, for example, when the rod and crank are in the same direction, which occurs twice at every rotation, no force whatever is transmitted by it, and the primary one is entirely suspended or held in equilibrium by the resistance of the fixed centres on which the crank and rod turn.

In the steam-engine the rod and crank are so adjusted that these two neutral positions occur when the piston is at one or the other end of the cylinder, and the valves are so arranged that, both steam passages being closed, all communication between the engine and the boiler is cut off; otherwise the steam, which could not under these circumstances move the piston, would exert its force to the detriment of the machine; as soon, however, as the momentum of the fly-wheel has carried the crank past these positions, the motion reciprocally imparted through it to the piston and valves admits the entrance of the steam from the boiler into the cylinder again. It is one of the important details in the construction of the engine, that the piston should be in that point of its course when the steam exerts its maximum of effect on it, at the time when, the rod and crank being at right angles to each other, the maximum of force may be exerted to turn the fly-wheel.

Since the diameter of the circle described by the crank must be equal to the length of the stroke, or to the distance through which the piston moves, it might be thought advantageous to increase the length of the stroke, as admitting of a longer crank; but there are limits to this length, determined by a variety of circumstances, some of which will be hereafter explained.

When Watt substituted the elastic force of steam for the pressure of the atmosphere, he introduced a source of power which might be increased to an indefinite extent, provided it were found advantageous to employ it; and the question naturally suggests itself, what is the elastic force or pressure at which the maximum of useful effect can be produced with a minimum expenditure of fuel? Unfortunately no direct answer can be given; in mathematical language, the unknown quantity is a function of too many variables to be capable of determination, except by repeated experiments for every specific engine, this quantity varying with the principle of its construction, even with the details. The results of such experiments seem to show, that generally it is more advantageous to employ steam of a comparatively high elastic force; accordingly the pressure was increased, in engines constructed by Watt, from 4 to 8 or even 12 lbs. on the inch, the apprehension of danger from the explosion of boilers in which steam of high pressure was generated constituting the chief limit to a further extension of the practice; at the present day condensing engines are even worked as high as from 25 to 30 lbs. pressure. The nature of those improvements in the construction of boilers will be briefly explained hereafter, by which steam of 200 lbs. on the inch may be generated, if requisite, with nearly as much security as that of 4 lbs. in the earlier boilers; but at present, simply stating that such is the case, we proceed to explain some important changes which have been consequently made in the principles of the engine.

When the steam is first admitted into the cylinder, the total space filled by the steam is immediately augmented by that through which the piston moves; and if the capacity of the boiler were not several times greater than that of the cylinder, the consequence would be a gradual diminution of the pressure, supposing the total quantity to remain the same: but the moment the pressure in the boiler tends to diminish, an additional quantity of water passes into the state of vapour, of the same tension as that previously generated, provided the temperature be maintained; hence the pressure on the piston may be regarded as sensibly the same throughout the whole of its stroke, provided that pressure be somewhat greater than that of the atmosphere, and the communication with the boiler remain open. It must not, however, be supposed that the pressure on the piston is the same with that of the steam in the boiler; all that is here asserted is that the pressure on the former will be uniform.

But if the pressure be considerably greater than that of the atmosphere, the steam, even when separated from the water, while expanding in the enlarging space formed by the motion of the piston, will exert sufficient force to continue that motion, till at last the pressure diminishing inversely as the space increases, and directly as the temperature, according to Mariotte's and Gay-Lussac's laws, that pressure will finally be not in equilibrium with the resistance, and all motion will cease. This is the important principle of working engines, originally proposed by Watt, though not employed by him, but which now, from the improvements in boilers above alluded to, is becoming general under the name of that of *expansion*. In the common engine, if the pressure on the piston continue uniform during the stroke, as it would do if the communication with the boiler remained open, the piston would move with an accelerating velocity till it arrived at the end of the cylinder, when the motion in that direction being suddenly stopped, the momentum must be expended on some of the fixed points of the machine, to its manifest injury, and with the useless expenditure of so much power; accordingly the communication with the boiler is now always cut off when the piston has arrived at a certain point, and with a momentum sufficient to carry it to the end of its stroke without any useless expenditure of force, while the steam behind it, which was originally of but a few pounds pressure above that of the atmosphere, thus limited in quantity, rapidly declines in force, and ceases to urge the piston on. But on the "expansion principle," when the steam possesses considerable elastic force, the communication with the boiler may be cut off much sooner, and the piston is urged forward by the expansive force of the steam, which, although decreasing as the space increases, is yet sufficient to carry the piston to the end of the stroke.

If it be asked how it is advantageous to use half the quantity of steam at twice the pressure, when it takes perhaps twice the quantity of fuel to raise the steam to the double pressure, the answer is, that it can be shown analytically that the total force exerted by steam acting expansively is greater than that which would be exerted by steam of a constant pressure, equal to the mean of those exerted, first, at the moment the steam-valve is closed, and, secondly, when the piston arrives at the end of its stroke; consequently, as less steam may be used to produce the required effect, a saving of fuel is the result, or in other words, the quantity of steam may be much less than half, at double the pressure, or the pressure much less than doubled, to produce the same effect.

As long as a continued force of any kind produces a continued motion with a constant velocity in any body, the force must be in equilibrium with the resistance it has to overcome; for if the force were greater than the resistance, it would produce an accelerating motion, which is contrary to the supposition: and if the resistance became greater than the force, the velocity would retard till the equilibrium were produced: as long, therefore, as a steam-engine is moving with a constant velocity, the *pressure on the piston* must be equal to the resistance to be overcome, consisting of the net work to be done, together with the friction of the various parts, the resistance of the uncondensed steam, of the air on the opposite side of the piston, and of other sources of resistance, which all concur to produce the gross resistance to be overcome. Putting P' for the pressure of the steam on each unit of surface of the piston, and R for the resistance for the same unit, or for the quotient obtained by dividing the total resistance by the number of units of surface, we have

$$P' = R \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (A)$$

as the first equation of condition; but since the velocity of the motion must be taken into consideration, when the *power* or force of the engine is to be determined, we must consider the velocity with which this pressure is applied, or, in other words, the rate at which the steam is applied to the cylinder; and it is obvious that when the engine is moving with a constant velocity, the supply to the piston must be exactly that produced in the same time by the evaporation going on in the boiler. If, therefore, S expresses the volume of *water* evaporated in a unit of time and transmitted to the cylinder, and m the ratio of the volume of *steam*, formed under the pressure P in the boiler, to the volume of *water* which produced it, mS would express the volume of steam generated in each unit of time under the pressure P: by passing into the cylinder this steam assumes the pressure P', and, neglecting the further change produced by the variation in the temperature of steam in changing from pressure P to pressure P', the volume of that quantity of steam would be inversely as the pressures by Mariotte's law; consequently the volume mS, when transferred to the cylinder, would become $mS\frac{P}{P'}$; and putting v for the velocity of the piston and a for its area, av will be the volume of steam expended in each unit of time; hence we get

$$av = mS\,\frac{P}{P'} \quad . \quad . \quad . \quad . \quad . \quad . \quad (B)$$

eliminating P' between equations (A) and (B), we obtain

$$v = \frac{mS}{a} \cdot \frac{P}{R}$$

$$R = \frac{mSP}{av}$$

$$S = \frac{avR}{mP}$$

for the *velocity*, *resistance*, and *evaporation*, when the other quantities are known; it must be observed, however, that the element neglected in these general deductions, namely, the change produced by the variation in temperature, has an important influence on the result, and must therefore now be taken into account.

$$\mu = \frac{1}{n + qp} \quad . \quad . \quad . \quad . \quad . \quad . \quad (C)$$

is the general expression for the steam during its action in the engine, μ being the volume, and p the pressure, and n and q constants, determined by experiments, for different kinds of engines.[*]

Let a certain volume of *water*, S, be converted into steam of the pressure p, and let M represent the volume of *steam* produced, then—

$$\mu = \frac{M}{S} = \frac{1}{n + qp};$$

if M' and p' stand for the volume and pressure of steam from the same volume of water S, under other conditions, then—

$$\mu' = \frac{M'}{S} = \frac{1}{n + qp'};$$

and therefore the ratio of the volumes of steam produced under these different conditions from the same volume of water will be—

$$\frac{M}{M'} = \frac{\frac{n}{q} + p'}{\frac{n}{q} + q} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (D)$$

that is, the volumes will not be inversely as the pressures simply, according to Mariotte's law; but inversely as the pressures augmented by a constant.

From the above equation we get—

$$p = \frac{M'}{M}\left(\frac{n}{q} + p'\right) - \frac{n}{q} \quad . \quad . \quad . \quad . \quad (E)$$

Let P = pressure of the steam in the boiler.
P' = pressure of the steam in the cylinder; $P' < P$ *generally*.
π = pressure at any instant when acting *expansively* in the engine.
l = length of the stroke.
l' = the length of that part of stroke performed before the communication between the boiler and cylinder is cut off.
λ = the length of that portion of the stroke performed when the pressure is become π.
a = area of piston.
c = *clearage*, or space in the cylinder at each end left between the piston and the ends of the cylinder, including the part of the steam-pipe between the slide-valve and the cylinder, which space is necessarily filled with steam at each stroke.

When the piston has performed λ of its course under the expansive force of the steam, let $d \,.\, \lambda$ be the differential of this length, then the corresponding *force* or effect will be $\pi a d \,.\, \lambda$: and at the same instant the space $a(l'+c)$ occupied by the steam before the expansion will become $a(\lambda+c)$. Hence from (E)—

$$\pi = \left(\frac{n}{q} + P'\right)\frac{l'+c}{\lambda+c} - \frac{n}{q};$$

$$\text{and} \quad \pi a d \,.\, \lambda = a(l'+c)\left(\frac{n}{q} + P'\right)\frac{d \,.\, \lambda}{\lambda + c} - \frac{n}{q}\, a d \,.\, \lambda.$$

Integrating between the limits l' and l, we obtain

$$a(l'+c)\left(\frac{n}{q} + P'\right)\log\frac{l+c}{l'+c} - \frac{n}{q}\,a(l-l')$$

for the value of the total effect produced by *expansion* from the moment when the communication with the boiler is cut off, to the end of the stroke. By adding to this therefore the effect $P'al'$, produced previously, we get

$$a(l'+c)\left(\frac{n}{q} + P'\right)\left[\frac{l'}{l'+c} + \log\frac{l+c}{l'+c}\right] - \frac{n}{q}\,al = aRl \quad . \quad . \quad (F)$$

If in this expression, $l'=l$, which is equivalent to supposing the engine to be working without expansion, we get $P'=R$, as it ought to be.

Resuming the equation $\frac{S}{n+qP'}$, which expresses the volume of steam at the pressure P' furnished by the boiler in the unit of time, and $a(l'+c)$ being the volume of this steam expended at each stroke; then if there are K strokes in that time, the expenditure of steam will be

$$Ka(l'+c);$$

and if v be put for the velocity of the piston, we have $v=Kl$, or $K=\frac{v}{l}$; hence, by substitution, the expenditure will be

$$\frac{va(l'+c)}{l} = \frac{S}{n+qP'} \quad . \quad . \quad . \quad . \quad . \quad (G)$$

by equating the expenditure to the volume furnished by the boiler, which, as has been above stated, must be the condition when the

---

[*] It can be shown that the density and relative volume of a vapour, whether or not in contact with the liquid, may be deduced, if its pressure and temperature are known; and that when in contact with the liquid, the temperature varies directly with the pressure. In deducing formulæ for the steam-engine, it is necessary to be able to determine an expression for the relative volume of the steam in contact with the water, or the volume of the steam at the maximum of density and pressure at any proposed temperature. Now this cannot be done from the existing formulæ for analytical reasons, and it becomes necessary to adopt some empirical formula, for determining this relative volume of steam at its maximum of density, in terms of its pressure only; this formula must be tested by its conformity with experiment. The late M. Navier proposed for this purpose,

$$\mu = \frac{1000}{0{\cdot}09 + 0{\cdot}0000484\,p}$$

in which μ is the ratio of the volume of steam to an equal weight of water, and p the pressure; but this formula, though true within certain limits of pressure, is not consistent with experiments at pressures lower than the atmospheric, and the following is propounded by M. de Pambour, as more correct and comprehensive:—

$$\mu = \frac{10000}{0{\cdot}4227 + 0{\cdot}00258\,p} \text{ for condensing engines;}$$

$$\mu = \frac{10000}{1{\cdot}421 + 0{\cdot}0023\,p} \text{ for non-condensing engines;}$$

p being the pressure in pounds on the square foot. These formulæ in general terms therefore are expressed by

$$\mu = \frac{1}{n + qp} \text{ as in the text.}$$

motion is uniform. Eliminating P' between (F) and (G), we get for the final general equation—

$$v = \frac{\text{S}}{a} \cdot \frac{1}{n + q\text{R}} \left[\frac{l}{l' + c} + \log \frac{l + c}{l' + c} \right] \quad . \; . \; . \; (\text{H})$$

The resistance expressed by R in this formula is the *total* pressure on each unit of surface of the opposite side of the piston, and is composed of three parts. First, of the *load*, or work to be moved or done, which we will denote by r. Secondly, of the resistance arising from the friction of the engine, which may be expressed by $f + \delta r$; f being the friction when there is no load, and δr the increment due to the additional friction for each unit of the load r. And, lastly, of the pressure on the opposite surface of the piston, which will be the atmospheric pressure in non-condensing engines, or that of the uncondensed steam and residue of air in condensing ones; this we shall call p. All these, r, $f + \delta r$, and p, refer only to each unit of surface of the piston, or

$$\text{R} = (1 + \delta)\, r + p + f,$$

by substituting this value for R in (H), and putting k for

$$\left[\frac{l}{l' + c} + \log \frac{l + c}{l' + c} \right],$$

we obtain

$$v = \frac{\text{S}}{a} \cdot \frac{k}{n + q\,[(1 + \delta)\, r + p + f]} \quad . \; . \; . \; (\text{K})$$

Now the quantity $\frac{\text{S}}{n + q\text{R}}$, it will be seen (C) is the total space occupied by the steam (in contact with the water), under the pressure R: hence to deduce the velocity v, the volume of steam corresponding to the volume of water S, supposed to be converted into steam under a pressure equal to R, must be calculated; and this volume being divided by a, the area of the piston must be multiplied by k.

The equation thus deduced shows the relation between all the quantities, known or sought, that enter into the mechanical theory of the engine in its most general form: it should be observed however that to preserve homogeneity, the dimensions a, l, l', should be expressed in the same unit as the volume S of the water evaporated; and the pressures P, r, and p referred to the same unit as S.

When this formula is used for computation, it must be understood that the quantity S expresses the *effective* evaporation; that is, the volume of water which really passes to the cylinder in the form of steam, and which acts on the piston, and does not allow for any loss by leakage or from any peculiarity in the structure of the engine.

If the engine be a condensing one, acting expansively, l' must be made equal the length at which the steam is cut off; if expansion be not employed, l' must be made equal to l, or to the whole length of the stroke, in which case the quantity k becomes $\frac{l}{l + c}$, and the expression for the velocity becomes

$$v = \frac{\text{S}}{a} \cdot \frac{l}{n + q\text{R}} \cdot \frac{1}{l + c}.$$

The part p of the quantity R must be made equal the pressure of the uncondensed steam, &c. If the engine be a non-condensing one, then p will be equal the atmospheric pressure.

Since from (K) we obtain

$$ar = \frac{\text{S}k}{(1 + \delta)\, qv} - \frac{a}{1 + \delta} \left(\frac{n}{q} + p + f \right) \quad . \; . \; (\text{L})$$

it might be supposed that when $v = 0$, the resistance would be infinite, a paradox which would appear to vitiate the correctness of the formula. But it must be borne in mind that when $v = 0$, $\text{S} = 0$; for S is the quantity of steam which passes through the cylinder in each unit of time: and since no quantity of steam, however small, can pass without moving the piston, as long as S has any real value, v will have one too: when therefore $v = 0$, $\text{S} = 0$ also; and then

$$ar = \frac{0}{0}, \text{ and not} = \infty;$$

that is, the formula becomes indeterminate, but not the less direct, as will appear by considering the other quantities it involves, and the consequences of putting $v = 0$.

By supposing the velocity zero, it is, in the first place, evident that no steam can pass to the cylinder, as has been stated; consequently there can be no expansion, that is, $l = l'$. Again, the velocity being zero, the piston at rest becomes equivalent to the fixed sides of the boiler, and the pressure it sustains is equal to that in the boiler.

The working of an engine may be considered under three conditions: first, when it is working with a given pressure of steam, and with any, whatever, load or velocity. Secondly, when it is working with a given pressure, and with that load or velocity compatible with the production of a maximum of useful or net force with that pressure: this may be termed the *relative maximum of useful effect.* And thirdly, when the pressure having been determined to furnish the force most consonant with the action of steam in any specific engine, the load is regulated so as to be that most advantageous for that pressure: this last constitutes the *absolute maximum of useful effect* for that machine.

The three fundamental problems for solution in the calculation of steam-engines consist in determining the velocity, the load, and the rate of evaporation in the boiler, since the useful effect, or net available power, is a function of these three quantities; and this net available power may be expressed in six different ways:—

First, by the number of pounds raised to a unit of height in a unit of time.

Secondly, by what is termed the "horse-power" of the engine.

Thirdly, by the weight raised by the consumption of 1lb. of fuel.

Fourthly, by the weight raised by the evaporation of a cubic foot of water.

Fifthly, by the number of pounds of fuel, or of cubic feet of water, for each horse-power.

Sixthly, by the number of horses-power which is furnished by each pound of fuel, or by each foot of water.

For the various formulæ by which all these problems may be numerically solved for different kinds of engines, and for the investigations by which those formulæ are deduced, we must refer to more comprehensive works; contenting ourselves here with deducing the general equations for the other unknown quantities of evaporation, useful effect, and horse-power, as we have done for velocity.

From (K) we obtain

$$\text{S} = av \frac{n + q[(1 + \delta) r + p + f]}{k} \quad . \; . \; . \; (\text{M})$$

as the expression for the evaporation of which an engine must be capable to overcome a given resistance r, with a proposed velocity v, S being the quantity of water which is to be converted into steam and transmitted to the cylinder in each unit of time.

The useful or net force of the engine generated in the same unit of time is obviously arv; since v, the velocity, is in fact the space moved through by the piston in that time; by multiplying therefore both sides of (L) by v we obtain

$$\text{Useful force} = arv = \frac{\text{S}k}{(1 + \delta) q} - \frac{av}{1 + \delta} \left[\frac{n}{q} + p + f \right] \quad . \; . \; (\text{N}_1) \text{ or by}$$

multiplying both sides of (K) by ar, we obtain an expression for the same quantity in terms of the load

$$\text{Useful force} = arv = \frac{\text{S}rk}{n + q[(1 + \delta) r + p + f]} \quad . \; . \; (\text{N}_2)$$

It will be noticed that for any proposed engine this force does not depend on the pressure of the steam in the boiler, P not entering into these expressions; but on the evaporation S effected in the boiler in each unit of time.

What is termed a "horse-power" is estimated as 33,000 lbs. raised one foot in a minute [HORSE POWER]: by dividing therefore the equations last obtained by 33,000, we get

$$\text{Useful force in horse-power} = \frac{\text{Useful Force}}{33000}.$$

and if during the unit of time N lbs. of coals are used in the furnace,

$$\text{Useful force from 1 lb. of fuel} = \frac{\text{Useful force}}{\text{N}}$$

We must now return to our general description of the engine and of its modifications.

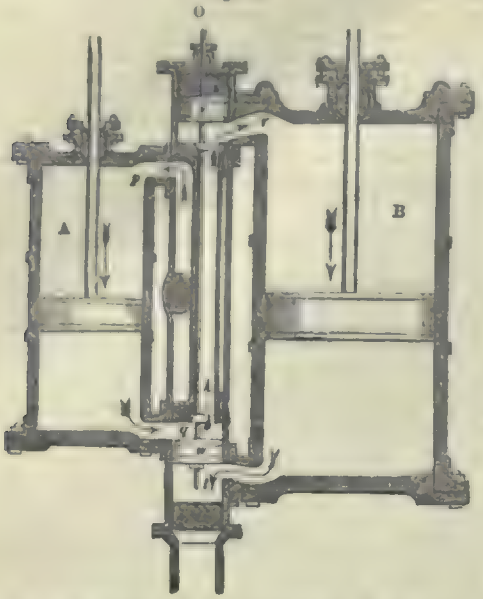
In 1781 an engineer named Hornblower proposed using the expansive principle by means of a double cylinder, but was prevented from carrying out his plan by the comprehensive and jealously guarded patents of Watt and his partners. In 1804, however, Woolf brought this principle of the double-cylinder engine into use. The annexed figure (*fig.* 11) will explain the mode of its action with an improved slide-valve.

The steam enters through the passage p *above* the piston in the smaller cylinder A, at a considerable pressure: while the piston is descending under its influence, the steam from beneath passes through the tube r *above* the piston in the large cylinder B, which is impelled downwards by its expansion, the steam which was previously under this piston having passed to the condenser by the passage t. When the stroke is completed, the slide is moved downwards by its rod o. The small plugs or pistons v and w pass below the openings r and t, and the slide below the orifices p and q, and the action is reversed.

But though possessing considerable advantages, the double-cylinder engine has not become common, unless in the case of large pumping engines, probably owing to the complication of its structure, and the increased effects of radiation from so large a surface, more than compensating its merits; and the expansive principle, equally applicable to a single cylinder, is now principally employed in engines of the common construction.

To reduce the compass and weight of the engine sufficiently to render it portable, the cumbrous apparatus of the condenser, and its attendant pumps and cisterns, had to be discarded; and since the principle of condensation was consequently renounced, it was necessary to raise the steam to a pressure sufficient to overcome that of the atmosphere on the opposite side of the piston. To allow the steam to act alternately on both sides of the piston, that which had just acted on one side to drive the piston was expelled into the open air through an orifice, corresponding to that which would have connected the cylinder with the condenser in an engine of the usual construction; but unless this orifice were as large as the diameter of the cylinder, which obviously it never can be, the steam, retarded in its escape by the contraction of the passage, must diminish, by its resistance to compression, the effective force of that which is acting to impel the piston.

Fig. 11.



Such is the simple principle, and such the greatest defect, of the non-condensing engine; but the saving in original cost and the paramount advantage of portability more than compensate for this defect; so that the use of this kind of engine has become general, not only for the purposes of locomotion, but for a variety of others where the engine is stationary, and probably in many instances where its advantages are imaginary.

Since the pumps of the condensing engine are dispensed with in the non-condensing one, the beam may be so likewise; the piston-rod is made to move in a straight line, by having a cross-piece attached at its top, which slides between *guides* fixed on each side of the cylinder, the rod which works the crank of the fly-wheel being attached to the end of this cross-piece. A still further simplification is effected by connecting the piston-rod directly with the crank on the shaft of the fly-wheel, the cylinder being mounted so as to oscillate as the wheel revolves on the steam passage, and thus alternately to open and close the communication between the top and bottom of the cylinder. Such engines are termed *vibratory*, and are successfully used where space must be economised, as with marine engines, but the weight of the cylinder thus moved is so much to be deducted from the power of the engine, and further causes a rapid wear of the centres on which it turns, which consequently cannot be long preserved steam-tight, and require frequent renewal.

Steam-engines are properly classed, according to the principle on which the physical properties of the steam are employed in them, into—

1. *Condensing Engines.*

1. Atmospheric engines, acting by	Condensation only.
2. Double-acting engines . . .	Pressure and condensation.
3. Double-acting engines . . .	Pressure, expansion, and condensation.

2. *Non-condensing Engines.*

1. Engines worked by	Pressure only.
2. Engines worked by	Pressure and expansion.

The form of the engine, the arrangement and construction of its parts, its power, &c., depend entirely on the purpose to which it is to be applied, and may be indefinitely diversified, but those most in use may be artificially classed thus—

1. *Condensing engines*, with beams and parallel motions.
   1. Without a fly-wheel, for pumping in mines, &c.
   2. „ „ Marine engines.
   3. With a fly-wheel, for working machinery.
2. *Non-condensing engines*, without a beam.
   1. Stationary, with a fly-wheel for working machinery.
   2. „ Rotatory engines.
   3. Locomotive engines, without a fly-wheel.

Marine engines, or those used for propelling vessels, are in this country generally condensing engines, their situation admitting the abundant use of cold water. The principal peculiarity in the arrangement of the marine engine is the position of the beam, which, for the purpose of economising room, is placed lower than the cylinder, and is double, there being one on each side; a rod from one end of each of these is connected with a cross-piece at the top of the piston-rod, the rectilinear motion of which is produced either by guides, or by a crank-arrangement, analogous in its action to the parallel motion. The other ends of the double beam are connected by a cross-piece, carrying in its centre the "rod" to work the crank on the shaft of the paddles. In all vessels of any magnitude, there are two engines complete, so arranged that while the rod and crank of one are in their neutral position, those of the other are in that of greatest effect. Two engines are necessary to equalise and continue the motion of the wheels; for in the marine engine, the paddles, instead of performing the part of fly-wheels to continue and control the motion of the piston, require the whole force of the engines to maintain their own motion, owing to the resistance they have to overcome. There is also this further advantage derived from two engines, that if one should be injured, the vessel may be still propelled by the other, and not be entirely dependent on her sails, as she would otherwise be.

It has been mentioned that there is a limit to the proportion between the diameter and length of the cylinder; the advantage that would accrue in gain of power by a long stroke being diminished by the greater radiation of heat from the larger surface diminishing the force of the steam in the cylinder; here therefore, as in every other calculation connected with the steam-engine, it is hardly possible to arrive at any formula or rule that can be invariably used. If the surface of the cylinder were to be made a minimum, with a maximum of capacity, we could readily determine that the length should be twice the diameter;[*] but we find that this proportion is not adhered to by the best makers; it varies from 3 : 1 to 2 : 1; but in the marine engine it is usually shorter; in some instances the proportion is 1 : 1·25.

The diameter of the cylinder of a marine-engine is usually greater, in proportion to its length, than it is in others, in order to obtain, by an increased surface of piston, that power which is unattainable by a long stroke, owing to the limited space which can be appropriated to the engine. Formerly, the apprehension of danger, where so many lives were at stake, prevented the use of steam of more than 4 to 6 lbs. on the inch in marine engines, and the expansion principle consequently could not be had recourse to. At present, the economy of using this principle has outweighed the apprehension in the minds of the owners of vessels, while the public, contented with the information that the engine is a condensing one, seldom inquire further, and conceive that the steam is at a low pressure in all marine engines, although, where the expansion principle is used, which it now extensively is, the pressure in the boiler is at about 30 lbs. on the inch above the pressure of the atmosphere.[†]

Engineers have always been induced, by the obvious advantage of a continuous over an alternating motion, to aim at contriving a steam-engine in which the steam should act directly to produce such a motion. It does indeed appear at first sight that, where the object of the engine is to produce a continuous circular motion of a fly-wheel, or of wheels of some kind, it would be desirable that the steam should be applied directly to impel the wheel, instead of having its force transmitted through a series of levers, necessarily increasing the friction and the cost of the engine. Watt accordingly patented more than one of such rotatory engines, and many others since have from time to time brought forward arrangements for the purpose, but none have come into permanent and general use. The fact is that, as can be easily shown, the employment of steam in this way is productive of a greater waste of power, with a greater increase of friction, than can be compensated by any real advantages. In all rotatory steam-engines

---

[*] Let l = length, x = the diameter, c = the capacity of the cylinder; since the concave surface is only gradually brought into contact with the steam, by the motion of the piston, its effects on the temperature may be considered as about half what it would be if the whole surface were at once exposed. Then the whole surface, including the two ends, being

$$\pi x l + 2\,\frac{\pi x^2}{4} \text{ and } c = \frac{\pi l x^2}{4},$$

we have for the surface affecting the temperature of the steam

$$\frac{\pi x l + \pi x^2}{2} = \frac{2c}{x} + \frac{\pi x^2}{2}$$

therefore

$$\pi x dx - \frac{2c dx}{x^2} = 0$$

and by substituting the value of c, and reducing $2x = l$.

[†] On the Mississippi the boat-engines are worked with steam of from 100 lbs. to 130 lbs. on the inch; but the latter enormous pressure is rarely exceeded, "except," as an American commander said, "on *extraordinary occasions.*"

hitherto proposed, the principle has been to admit the steam to act on a fan or fans revolving round an axis of the cylinder; and, by ingenious excentric movements, the surface of these fans is made to increase as the steam diminishes in elastic force from the enlargement of the space it occupies. Many such engines have been used for a time, but commonly after a few years' trial they have been abandoned, and the reciprocating principle substituted, thus proving that experience confirmed the deductions from theory.

In all mechanical combinations, the object to be effected necessitates a certain characteristic form of the machine, which it retains, whatever improvements may have been successively introduced either in its principle or in the details of its construction. We can recognise in a modern Sussex plough the general form of that used by the subjects of the Pharaohs to till the banks of the Nile; and Newcomen would acknowledge a marine engine made by Maudslay and Field as a descendant of his atmospheric one: but he would for some time be at a loss to tell the object of a locomotive engine of Stephenson's, if he could see it at rest only, and the connection between it and its tender would be beyond his comprehension. The reason of this is, that a locomotive engine is a perfectly new application of the power, having no other analogy to an ordinary engine except that steam is the source of power in both; but all locomotive engines will hereafter possess a family likeness.

The principal causes of this novelty of form are, that great velocity being the object, the boiler must constitute the greatest part of the bulk, in order to supply a sufficient quantity of steam to meet the demands of the two pistons making 200 strokes per minute, and even then it requires a *tender* to accompany it to carry a supply of fuel and water to keep up the quantity. The locomotion is usually produced by a pair of *driving-wheels* made to revolve by the engine by means of cranks on their axle, receiving motion almost directly from the piston-rods; the adhesion which takes place between these wheels and the edge-bars or rails, causes the carriage to move on, just as the paddle-wheels of a steam-boat propel the vessel by the resistance of the water to the float boards. The driving-wheels of a locomotive engine do not, any more than the paddle-wheels of a steam-boat, act as fly-wheels to regulate the velocity of the engine; this is effected in the former by the inertia of the whole mass; the great velocity consequently ensures the steady action of the engine. In the steam-boat this great velocity of the paddles is unattainable, and consequently two powerful engines are requisite to maintain even a moderate velocity; but air being the medium in which the driving-wheels of a locomotive engine act, almost any velocity can be imparted to them, and for obvious mechanical reasons is best attained by steam acting with a force almost amounting to impact on small pistons through a short stroke, two alternately acting cylinders being necessary, as in the steam-boat, to equalise the action of the cranks.

The two internal cylinders are most conveniently placed under the boiler in nearly a horizontal position; intermediate cranks preserve the rectilinear motion of the piston-rods, and connect them with the cranks on the axle; while excentric frames on this axle actuate the simple slide-valves required in a non-condensing engine. The steam which is driven out of the cylinder at each stroke, instead of escaping directly into the open air, passes into the funnel of the furnace, and thus increases the draught; but as the action of the engine cannot be understood independently of the boiler, it becomes necessary to turn our attention to that subject, without a general description of which, any account of the steam-engine would be incomplete.

Upon the South-Western Railway of England, and on the Chemins de Fer de l'Ouest of France, the engines employed are made with external cylinders, and the piston-head is connected with the crank fixed on the driving-wheel by a link or connecting-rod. There are great advantages in this system, so far as economy of construction is concerned; for the cranks are simply keyed on the ends of the axles of the driving-wheels, instead of being forged upon the axles themselves, and the whole of the machinery is of a simpler and more efficient character; but at the same time the condensation in the cylinders is far more serious than it would be in the case of internal cylinder engines, on account of the more exposed position of the external cylinder engines. The latter engines, it may be added, present the advantage of having a smaller dead weight, per horse-power exercised, than is the case with internal cylinder engines.

Since some of the principal objects to be kept in view in the construction of boilers are incompatible with each other, one or more must be dispensed with in order to secure the rest. The specific purpose for which the engine is constructed must determine the general principle of the boiler: thus, rapid generation of steam, security, compactness, and lightness must be aimed at in boilers for marine or locomotive engines, even at the cost of a comparative waste of fuel; while for those intended for pumping or driving machinery, economy of fuel must be the paramount object, the weight, form, and space occupied by the boiler being secondary considerations. And whenever steam of a high elastic force is to be used, that form of boiler should be adopted which will most nearly equalise the strain on it. The following requisites are therefore to be understood as being those which it would be desirable to combine, though, united, they are unattainable in practice.

First, the boiler should have the greatest capacity with the least surface, to save material, diminish the weight, and increase the strength: hence a spherical form would be best in this respect, but it is incompatible with an economical application of the heat to a great extent of surface, which is essential to the rapid generation of steam.

Secondly, the form should be as simple as possible, both for the sake of reducing the expense of construction and most readily admitting of repair. Boilers are made of iron or copper plates riveted together at their edges; and if one of these is cracked, or has been burnt, that plate can be taken out and another put in without pulling the whole to pieces, which must be done when the boiler is of a complex form; added to which, all angles are sources of weakness, owing to the inequality of the strain on the adjoining surfaces, and the injury done to the metal by bending it to form the angle.

The form of boiler used for Savery's, Blakey's, Newcomen's, and other engines of the 17th and 18th centuries, up to the time of Watt, was that of an inverted frustum of a cone, with a spherical top, and its bottom slightly concave. This boiler was set in brick-work like a common copper, the flame playing round the whole of the lower part. The steam-pipe was connected in the usual way to a flange of a collar in the spherical head. Watt adopted a long rectangular form, with a semi-cylindrical top; the ends were flat and upright, the sides slightly curved inwards, as was also the bottom. From this form it is termed the *waggon-head* boiler. It is set in a rectangular mass of masonry, the cylindrical head alone projecting above the level of the brick-work; the fire-place was underneath one end of the boiler, and extended backwards for one-third of its length; the flue, after proceeding to the further end, returned along one side, across the end, over the furnace, and along the other side into the chimney-shaft, the boiler itself everywhere forming one side of the flue, and consequently having the flame and heated air directly in contact with it at the bottom and sides. In some cases, when the boiler was very large, a cylindrical iron flue was formed through the boiler longitudinally, opening at each end into and forming a continuation of the brick one, thus increasing the surface to be acted on by the heat.

The next important modification in form was that of making the boiler entirely cylindrical with hemispherical ends, which is probably the form best fitted to combine as many requisites as possible. With this form the furnace is often placed in a second cylinder within the boiler, and forming the first part of the flue: thus the fuel being entirely surrounded by the water, little or no heat is lost by radiation; but there are serious objections to this practice on the score of accidents, as well as the deficiency in draught, owing to the confined space in which the combustion takes place.

When an engine is of such a size as to require more steam than one boiler of the ordinary magnitude can supply, it has two or more, set side by side, communicating with a common steam-pipe. Since the extent of surface exposed to the pressure of the steam, and therefore the liability to bursting, increases in a greater ratio than the capacity, there is obviously a limit to size, which can never safely be surpassed, while the security is proportionally increased by diminishing that capacity: hence the necessity for using two or more small boilers instead of one large one; and the principle, carried to its limit, constitutes that of the *tubular boiler*, in which the steam is generated in a series of independent metal pipes of small diameter, all communicating with a common steam-chamber or reservoir, itself small, and strong enough to resist great pressures.

These tubular boilers, however, have not come into general use, not only on account of their complexity, and consequent liability to derangement, but because, unless in the case of locomotives, or steam-boat engines, there does not exist any demand for steam of such high pressure as they are intended to generate.

Since, in accordance with the general hydrostatic law, every unit of surface of the boiler has to sustain the same pressure, if a small portion of that surface can be opened by the pressure of the steam, when it has attained that which the boiler was only intended to withstand, by the escape of a quantity of the vapour at this orifice, the elasticity of the remainder is again reduced below the limit. This is the object of the *safety-valve*, which is such an aperture, kept closed by a valve retained in its seat by a weight calculated to yield to, or be raised by, the pressure the moment the steam exceeds its proper elastic force.

The safety-valve was first contrived by Papin, and used in his digester and boilers, and has ever since constituted an essential appendage to every boiler. In its simplest form it is an obtuse conical valve, kept in its seat (which is at the end of a short collar, standing up from the surface of the boiler) by a weight acting at the end of a lever, resting on the spindle of the valve, and having its fulcrum or hinge at the other extremity. The effective weight by which the valve is kept down may be varied by shifting the position of the weight on the arm of the lever; and as this alteration might be unintentionally made by carelessness or accident, the valve should be inclosed in a box under lock and key, to prevent its being tampered with. A chain attached to the valve, and accessible to the engineer, should be provided, to enable him to raise the valve, to ascertain that it is in efficient order, and has not become fixed in its socket. But the best mode of applying the weight is directly on the valve, so that it cannot be increased, as long as it is inclosed, by any accidental alteration in its position. In locomotive engines the weight would be liable to derangement by the motion, and a spiral spring is employed to keep down the valve.

The safety-valve is perfectly effective as long as it is free to rise in its seat, and is loaded with a constant weight, which ought never to be more than one-third the pressure the boiler is just capable of withstanding. The rapid diminution in the number of accidents from explosions, notwithstanding the increased employment of steam, sufficiently proves that they are nine times out of ten caused by gross negligence or culpable recklessness; but to obviate as much as possible the recurrence of explosions, every boiler should have at least two safety-valves, both secured from access, and yet both capable of being raised by hand from time to time: one should be loaded with a less weight than the other, that by the escape of the steam from it the engineer may be warned to reduce the quantity of steam generated, by "damping" his draught; and the other safety-valve should be only loaded with a weight equivalent to one-third the pressure which, by computation founded on actual experiments, would burst the boiler, if made with metal of a given thickness; for, however carefully the boiler may have been made, it is impossible to ensure equal strength of it in every part.

A plan was originally suggested by Trevithick for insuring safety from a boiler by inserting in it a plug of metal, which, melting at the temperature attained by the steam when its tension became dangerous, might open an exit for it. This plan is adopted in France, but besides that it is repugnant to our ideas of mechanical fitness, it is liable to many objections; none of the pure metals melt at a temperature sufficiently low to be available, and all the fusible alloys soften long before they melt, and vary in these respects with minute differences in the proportion of their ingredients, so that the plug might be driven out before the proper time.

The boiler, besides the danger of bursting from over-pressure of the steam within it, is also liable to injury by the external pressure of the air, if the steam within be condensed, as it must be on cooling, when the fire is let out, thus causing a comparative vacuum in the boiler. To guard against this, there should be a safety-valve to act in the direction opposite to the usual one, which, yielding to the pressure of the atmosphere, would allow of the entrance of the air, when this pressure exceeded the one exerted by the steam to keep the valve closed.

Another source of accident, which should be guarded against most sedulously, is the formation in the boiler of a deposit of the earths, &c. chemically united with the water or held suspended in it, and which are deposited from all water when long kept boiling in any vessel, as is illustrated and proved by the furring of old tea-kettles. This deposit is intensely hard, and adheres so closely to the metal, that it requires a chisel and hammer to detach it when accumulated to any thickness. Being a bad conductor of heat, it prevents the rapid generation of steam, and by not allowing the water to be in contact with the metal, so as to carry off the heat imparted to the latter, the metal gets red-hot and is burnt, or, in chemical language, becomes oxidised by long exposure to a high temperature. If, under these circumstances, a fissure should be produced in the earthy crust, the water, suddenly admitted to contact with the red-hot iron, is converted instantaneously into steam of such high pressure as to risk the bursting of the boiler.

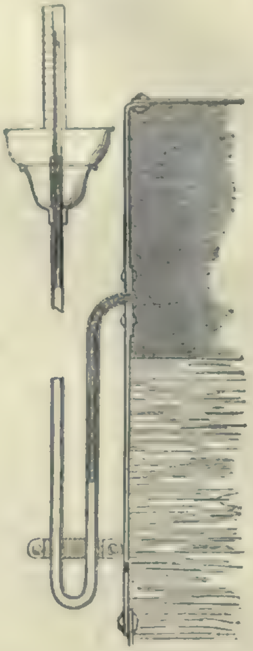
It is one of the advantages held out as an inducement to their adoption by the inventors of tubular boilers, that, owing to the inequality of the temperature of the liquid at different distances from the source of heat, a circulation is continually going on, which mechanically prevents the formation of a deposit, while in large open boilers no such cause can operate to any extent. In these the remedy appears to be the frequent cleaning out of the boiler, to prevent the accumulation of the deposit, and the admission of the water which supplies the waste to the part not over the furnace, which should be separated from the rest by a partition extending upwards nearly to the level of the water; the fresh water is thus allowed to deposit its sediment in the part where it can be least productive of the evils alluded to, and whence it may be removed collectively from time to time.

To indicate the actual pressure at any time of the steam within the boiler, this is furnished with a *gauge* (*fig.* 12), consisting of a bent tube, open at both ends, one orifice A opening into the boiler. This tube contains mercury, which will obviously be at the same level in both branches when the steam in the boiler is of the same pressure as the atmosphere, but will rise in the longer leg as the pressure of the steam increases, and will thus by its altitude indicate that pressure. If the longer leg be of a certain length, the mercury would flow over, or be blown out; altogether, if the steam were suddenly to increase in its elastic force, the gauge would in this case act as a safety-valve. The loss of the mercury may be guarded against, under these circumstances, by a cistern placed round the orifice of the gauge to receive it, as shown in the figure.

A water-gauge is often used instead of a mercurial one, to save the expense of this metal; but then the tube must be long enough to allow a sufficient column of water to balance the pressure of the steam; and by making the tube of sufficient diameter, this water-gauge then constitutes an efficient safety-valve. As these gauges cannot, for obvious reasons, be made of glass, to allow of the height of the fluid within them being directly observed, this height is indicated by a light wooden rod projecting beyond the end of the gauge, which floats on, and therefore rises and falls with, the mercury or water.

In locomotive-engines, where the use of a mercurial and still more of a water-gauge is impracticable, the same end is attained by a thermometer, on the well-known principle that the temperature of steam is always in a constant relation to its pressure; or by Bourdon's steam-gauge, in which the steam acts upon a diaphragm, as in the aneroid.

Fig. 12.



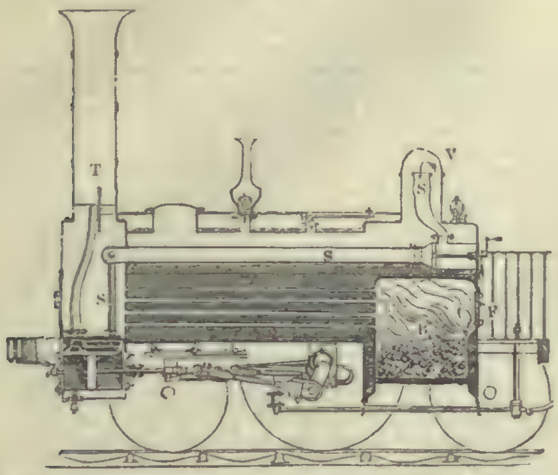
If there be not water in contact with that part of the boiler exposed externally to the direct action of the flame and hot air in the furnace and flues, the iron would become red-hot, and so suddenly increase the pressure of the steam in contact with it, that an explosion would probably ensue; and if not, the iron in that part would be more oxidised or burnt. To prevent this it is necessary that there should be always water in the boiler above the level of the highest part of the flues; and to enable the engineer to ascertain whether this is the case, there are in all boilers two pipes with cocks, one of which dips down into the water, while the other reaches only to within a few inches of its surface when at the right height in the boiler; the consequence of this arrangement is, that if the cock of the shorter pipe be opened steam will issue from it, and water from the other when that is opened in its turn; but if steam escapes from both cocks, the engineer is warned that there is not sufficient water in the boiler, and therefore directs his attention to remedy the deficiency.

The boiler is always supplied with water by the action of the engine; the hot water, pumped out of the condenser, is raised into a cistern placed at a sufficient height above the boiler, by the force-pump mentioned in the general description of Watt's engine; from this cistern a pipe passes through the top of the boiler, and reaches nearly to the bottom, where it is bent at right angles; the upper orifice in the cistern is closed by a valve connected by a spindle-rod with one end of a simple lever, from the end of the other arm of which a wire is suspended, supporting a stone float in the boiler, the valve being weighted just to counterbalance the specific gravity of the float; as the water subsides in the boiler in consequence of its evaporation, the float falls and raises the valve, allowing sufficient water to descend into the boiler till the float, rising again, causes the valve to close; the weight of the column of water in the pipe prevents the steam from escaping in that direction during the action of the valves; hence the necessity for the feeding-cistern being raised sufficiently above the boiler. The bend at the bottom of the feeding-pipe is intended to cause the water, when issuing near to the bottom of the boiler, to wash away the sediment which would otherwise collect there.

The locomotive-engine, as has been stated, requires a boiler of a form and principle totally different from those of an ordinary one.

The boiler A (*fig.* 13) is a cylinder made of wrought-iron plates, riveted together in the usual way, but it is covered with a wooden casing, to prevent, as far as possible, the great waste of heat which would radiate from a metal surface moving through the air with great velocity. At one end of the boiler is the furnace B, consisting of a double case, the outer one of iron with a semi-cylindrical head, but quite open at bottom; within this is an inner square case of sheet copper, riveted all round the bottom edge to the outer one, but leaving on its three sides a space of three inches between them, which is filled with water, and indeed forms a continuation of the boiler. The bottom of this inner case is the grating on which the fuel is laid. F is the feeding door in front, opening of course through both cases, which are therefore riveted together, so as to be steam-tight all round. A series of upwards of 100 brass tubes of small diameter pass from the back of the furnace to the further end of the boiler, where they open into the chimney. These tubes, which are entirely immersed in the water, constitute the flue, and thus increase considerably the heated surface in contact with the water, and therefore promote the rapid generation of steam. The introduction of these tubes forms an epoch in the construction of boilers, and was the suggestion of Mr. R. Stephenson, and simultaneously of M. Seguin, in 1829. [RAILWAY.]

Fig. 13.



The cylinders of the engine, of which one only can be seen in the section, are fixed at the bottom of the chimney. The steam passes to the slide-valve by the pipe S, S, while the waste steam escapes up the funnel at T. The cylindrical vessel with the spherical head V, is called the *steam-chest*, the steam-pipe terminating in it at S. The object of this arrangement is to prevent the water, which is agitated by the motion, from passing through the steam-pipe to the cylinder, where it would be highly detrimental; the main steam-pipe divides into two branches in the chimney, one passing to each cylinder.

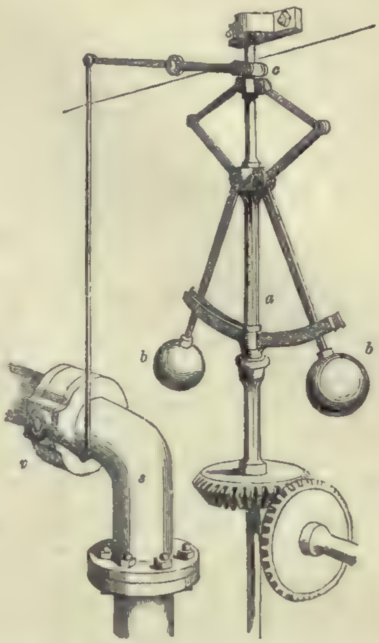
The boiler is supplied with water from the tender by two force-pumps worked by the engine, and has a gauge, try-pipes, safety-valves, &c., in common with other engines, though all peculiar in their construction.

This brief account of the boiler, and of its various arrangements, will hardly be considered complete without some notice of the explosions to which it is liable.

The bursting of boilers presents very different phenomena, being sometimes a simple rent in the metal, allowing the harmless escape of steam and water; and at others accompanied by an explosion in its violence equal to that produced by gunpowder; it has hence been conjectured that on these occasions some explosive gases are formed in the boiler; but this does not appear probable, nor is it reconcileable with any known physical laws, while the elastic force of steam is capable of indefinite increase, and is quite adequate to produce any mechanical effect whatever. It is always difficult to get any satisfactory evidence as to the facts of an explosion of a boiler; the terror of the moment prevents the survivors from accurately recalling the phenomena immediately antecedent, while those who from their proximity would be best capable of affording this evidence, are either killed, or are too interested in exculpating themselves to be impartial witnesses. With regard to the formation of explosive gaseous compounds in the boiler, it is generally admitted that hydrogen gas is the only ingredient of such that can be formed; and that is obtained by the decomposition of the steam when in contact with the red-hot iron; but pure hydrogen is not explosive; and to render it so it must be mixed with oxygen or atmospheric air. It has been suggested that the latter may be introduced along with the water by a defect in the feeding-pump; but the proportions of the air and of the hydrogen must be definite to produce an explosion; and it is difficult to suppose that in such a situation either should continue to accumulate till the quantity is exactly that necessary to produce an explosion. In short this explanation of the subject is beset with difficulties which have not yet been removed, though the attention of scientific men both in Europe and America has been frequently directed to it.

Whenever the steam-engine is employed to execute any work which is variable in its quantity or intensity, there must be some means of adjusting the force of the engine to this varying resistance it has to overcome: if the engine were suddenly relieved of half that resistance, as, for example, would be the case if half the machinery it was driving were suddenly stopped or thrown out of gear, the engine, if impelled by the same quantity of steam, would immediately move with a rapidly accelerating velocity, till that velocity were doubled, which would be prejudicial to the engine itself and to the rest of the machinery it was working, as well as be a useless expenditure of force or fuel. The object of that beautiful piece of mechanism termed the *governor*, is to enable the engine to regulate the supply of steam admitted to the cylinder, or in other words to adapt the force it has to transmit to the resistance it has to overcome.

Fig. 14.



The governor, the form and principle of which will be better understood from the figure (*fig.* 14) than from any description, is made to revolve on its vertical axis *a*, by a band passing round a pulley and round one on the axle of the fly-wheel, or else by bevilled wheels, as shown in the figure; so that its velocity of rotation varies with that of the fly-wheel. If this velocity increase, the heavy balls *b b* diverge by the increased centrifugal force, and cause the collar *c* to slide up the axis; this by means of the intermediate cranks partially closes the valve at *v*, in the steam-pipe *s*, termed the *throttle-valve*, and consequently diminishes the quantity of steam passing to the cylinder: if, on the contrary, the velocity of the fly-wheel is diminished by an increase in the resistance, the balls of the governor collapse, and the throttle-valve is opened so as to admit more steam to the cylinder to augment the force in proportion to the increased resistance.

The effect on the governor is equivalent to varying the diameter of a second fly-wheel, the circumference of which is represented by the balls *b b*, consequently the governor itself, independently of its action on the throttle-valve, has a tendency to effect the adjustment required; since a portion of the surplus force of the engine, on the first supposition, is absorbed in overcoming the increased inertia of the governor; while, on the second supposition, that inertia, being diminished, relieves the engine of a portion of resistance. This accounts for the prompt action of the governor in effecting the adjustment, which it does without those fluctuations in the velocity of the piston which would be prejudicial to the effect of the machinery actuated by this prime-mover.

In the marine engine no governor is requisite; the resistance being so great compared to the force, that the velocity can never be excessive, and all the power the engine is capable of exerting is required to turn the paddle-wheels; added to which the resistance is nearly uniform, only varying with the draught of the vessel or the state of the weather, but never diminishing below that originally calculated on and provided for by the power of the engines; an increase of the resistance accordingly produces a diminution in the velocity of the vessel, but the engine can never work so fast as to be injured by its own velocity.

The governor is equally unnecessary to the locomotive engine, since the attendant must constantly have the engine under his control, and be watching its action; he can therefore regulate the throttle-valve by hand-gear placed within his reach; and in this case also, as with the marine engine, the resistance is nearly constant, consisting chiefly in the weight of the engine and the train of carriages to be moved, a weight not liable to any sudden change during the transit, while the momentum of the whole mass acts as a fly-wheel or regulator to equalise the motion of the pistons.

We have not entered into any investigations of the formulæ for determining the dimensions of an engine and of its boiler, the pressure at which it must be worked, the velocity of the piston, &c., in order to produce any proposed available or net force; or into the account of the experiments by which the amount of friction, the effects of the uncondensed steam, the quantity of caloric obtained from different kinds of fuel, &c., all of which must be taken into account in these investigations, and have been approximatively determined.

(In the preceding article the formulæ expressing the physical and mechanical properties of steam will be found, and for the others the following works among others may be consulted: Tredgold, T., *On the Steam-Engine;* Farey, J., *On the Steam-Engine*, 4to.; De Pambour, F.M.E., Chev., *Théorie de la Machine à Vapeur*, 8vo., Paris; Galloway, *On the Steam-Engine*, and others.)

STEAM-CARRIAGES on common roads have for many years occupied the attention of engineers and mechanicians, on account of the evident economy which would result from the use of a road surface adapted to, and previously constructed for, ordinary traffic; but, up to the present time, none of the systems which have been proposed for the construction of these engines can be considered to have entirely overcome the practical difficulties attending the transport of the weights required in the machinery and boilers, or the variable resistances encountered. Some of the more recently introduced traction engines seem, however, to contain, in germ, the elements of the successful solution of the problem of steam locomotion, by engines of small power, running on roads possessing an inferior degree of theoretical perfection than well maintained railways; and the introduction of the street railways certainly justifies the belief that, ere long, steam-engines may be used upon them between points which would not require, or justify, the construction of regular railroads. A short notice of the most celebrated attempts to adapt steam-carriages to common roads may, therefore, be desirable, accompanied by a few remarks on the characteristic distinctions between the resistances to be overcome in the respective cases of rail, or of common, roads.

When steam-carriages work upon railroads, they traverse a surface of uniform hardness and rigidity; and it is easy to distribute the load over a number of carriages drawn by the engine, because the rails maintain the various parts of the train in the desired positions with respect to one another. No difficulty either occurs, in this case, on the score of the guidance of the engine or of the load; nor is it necessary to provide for avoiding obstacles in the road, or on account of sharp curves or bends. On common roads, however, the yielding nature of the surface imposes a limit to the weight brought upon the driving-wheels; and the state of the surface as affected by wet, by the addition of fresh metal, or by other accidental causes, must materially increase the irregularity of the resistance. The rates of inclination adopted on common roads, and the small radii of curvature frequently met with upon them, are far more unfavourable than those met with in railways; and it is found in practice that there are serious objections to the use of more than two carriages in immediate connection with one another on common roads; so that forcedly the space devoted to the reception of the machinery, boiler, combustible, &c., is confined within very narrow limits, in order to leave any space available for the conveyance of passengers or of goods. The irregularity of resistance of the road surface renders it necessary also to adopt great precautions in the construction of the parts of the engine designed to transmit motion from the piston-head; and the constant changes of inclination require that there should be provided, in steam-carriages designed to run on common roads, means for varying at will the amount of power exercised. In all locomotives it is desirable that the machinery should be of the simplest construction, and that it should be susceptible of easy examination and repair; but this is essentially the case with steam-carriages, on account of the variety of action required of them. The consequences of these peculiar conditions are that steam-carriages must be made to combine great power within small compass, and with small dead weights; they must be constructed so solidly as not to be deranged by the shocks, or the bad state of the roadway; and lastly, they must be able to work without producing any nuisance, or any interference with the ordinary horse traffic of the public thoroughfares. Hitherto it has not been found possible to secure these conditions, and to secure economy of traction at the same time; and the substitution of steam for animal power is still confined to railways, notwithstanding the enormous amount of capital they require to be expended on their construction.

It appears that as far back as 1786 attempts were made by William Symington, in Scotland, and Oliver Evans, in Philadelphia, to introduce steam carriages, or waggons, on common roads; and Mr. Murdoch, the well-known associate of Boulton and Watt, is said in 1782, or 1792, to have made a similar attempt. In 1802, Trevethick and Vivian produced an engine for the same purpose of much greater value than those previously made. After their trial, some years elapsed before other parties took up the question, and it was not until 1821 that Griffith patented his steam-carriage. In 1822 David Gordon began his public essays on the subject, and in the succeeding years he took out several patents connected with it. He was, in 1824, followed by many other inventors, such as Hancock, Summers and Ogle, Dr. Church, Sir J. Anderson, Sir C. Dance, Mr. J. Scott Russell, &c. The success of these experiments was, as might have been expected, of a varied character; but they seem to have roused a singular amount of local opposition, which finally assumed so violent a character as to lead to the nomination of a select committee of the House of Commons to inquire into the "present state and future prospects of land carriage by means of wheeled vehicles propelled by steam or gas on common roads." The report of this committee was published in October 1831. Although this report was favourable to the new application of steam-power, and although Mr. Hancock in 1831 produced a steam-carriage which, like the one proposed about the same time by Mr. Goldsworthy Gurney, answered to a great extent the anticipations of their inventors, the difficulties attending this mode of locomotion were considered to be so great, that about 1832 the conviction in the minds of practical engineers had become almost universal that "every attempt then made to render steam-carriages the means of economical and regular inland communication had totally and absolutely failed." The success of the railway system, then first applied on a large scale, served likewise to turn public attention from the avowedly inferior system of steam locomotion on common roads; and it was not until the recent application of steam-machinery to agricultural purposes had rendered it desirable to introduce some mechanical traction-engines of great power, that engineers were again induced to study this particular problem. In the Great Exhibition for 1851 there was only one plan of a locomotive for common roads; but between 1858 and the end of 1860 as many as nine varieties of those engines were submitted to the public, of sufficient importance to merit the attention of the professional journals and occasionally of the various departments of the government. Of these, Boydell's, Clayton's, Burrell's, Bray's, Giles's, and Stirling's traction-engines, Lord Caithness's steam-carriage, Aveling's self-propelling agricultural engines, and the engine made by Mr. Creswell for the English and Continental Traction-Engine Company, have attracted the greatest amount of notice, and some of them have actually performed good work. Bray's traction-engine, for instance, has been usefully employed in our dockyards. Lord Caithness reports that with his carriage, having cylinders of 3 inches diameter and 7 inches stroke, he was able to attain on the level a speed of 19 miles an hour, and to ascend inclines of 1 in 7, working at an average expense of from a halfpenny to a penny per mile; the weight, with water for a run of 12 miles, and coals for 20 miles, is only two tons; but the carriage only conveys (in the form represented in the 'Engineer' for Oct. 19, 1860) three passengers. Creswell's engine is said on one occasion to have drawn two waggons containing 10 tons of earth each up Pentonville Hill, a long incline of about 1 in 70; but on a repetition of the experiment it broke down. There seems, therefore, to be some reason for the belief so confidently expressed by Lord Caithness, that ere long steam may be substituted for horse-power on common roads; and as the prejudice against its use has, since 1831, been considerably diminished, the most bitter source of opposition has disappeared. The application of the expansion gear, and the introduction of street railways, must however be considered to have effected the greatest service towards the introduction of steam locomotion without the construction of special roadways. With all their modern improvements, steam-carriages are nevertheless still but imperfect substitutes for railway travelling, and it may almost be a subject for regret to witness the amount of energy, skill, and money expended upon them.

The best information on the construction of steam-carriages is to be found in Gordon's 'Treatise upon Elemental Motion;' Hancock's 'Narrative;' the 'Mechanics' Magazine;' the 'Engineer;' and the Reports of the Select Committees of the House of Commons in 1831, and 1834 and 1835, upon Steam-Carriages and upon Goldsworthy Gurney's claims.

STEAM NAVIGATION. It would seem that navigation, being founded on the bases of geometry and astronomy, would be but one system, practicable alike by the commander of a sailing ship or of a steamer; that practice attained in navigating one class of vessels would be equally available for the safety of the other; but it is not so. As well may we compare the driving of a spirited horse in a light gig to the driving of a waggon team: there are points of skill in each, and proficiency is also attainable in each, but interchange the drivers, and it is probable that neither of the vehicles would be so well conducted as before:—and thus it is with steam navigation. The sailor of the old school (for there is specifically a *new* one), is accustomed to have his eyes aloft; and the trim of his sails, and the steadying of a bowline here, and the pulling upon a brace there; the habitual look to windward for coming weather, &c.; these form the main sources of that unceasing vigilance without which no one can be fit to command.

The navigation of a ship (in its abstract meaning), is with the sailing commander a mere routine. A course of measured attentions to certain established customs, handed down from generation to generation, and performed at definite periods, leaves his mind, after those periods have passed, nearly free from the duties of calculation altogether. But in the new school, things are far different, and it will be useful in this place to illustrate the present state of the subject, by examining into what really constitutes this difference, for it becomes a question of training and qualification.

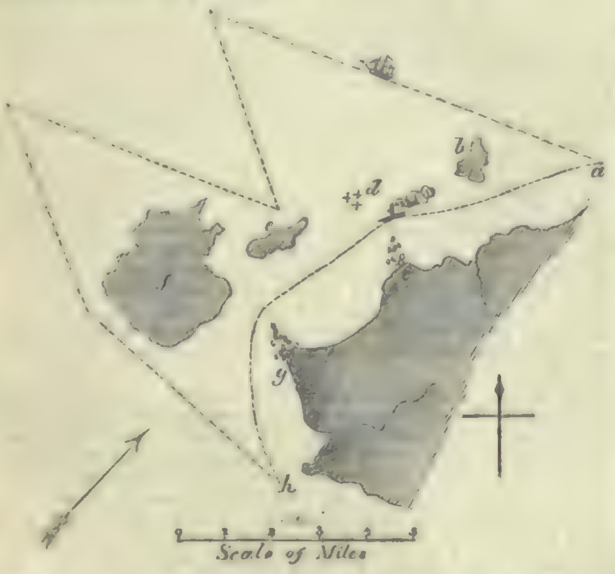
We have only to refer to our article Collisions at Sea, to show that fearful innovations have followed the introduction of steam into our sea services—affecting in a high degree the safety of life; and we also refer to Ships and Shipping to show what laws are found necessary in preventing such insecurity. Fearful then must be the increased responsibilities of a commander of a steam vessel. Nor does this admit of limitation, for the very causes of all this are in themselves progressive.

Very much may be attributed to the increase of speed in steamers; yet there are other influences which affect steam navigation with peculiar force: among these may be noticed the wide prevailing interest that owners, of steamers in particular, feel in the rapidity of their voyages. Hence, every advantage which can be taken to accomplish this, is considered part of a commander's duty—and his position, therefore, depends much upon his habitually making a quick passage.

The following will explain the work of each kind of navigator. In the sailing ship, the master daily at 1 bell in the forenoon watch (half-past 8 a.m.) takes his sextant upon deck to obtain an altitude of the sun, in readiness for working his time at ship: he defers this work till noon, at which he will have obtained his ship's latitude from a meridian altitude. During the forenoon, or from nine o'clock, his only work connected with navigation-proper, is an occasional glance over the side of the ship, in order to estimate the ship's "way" (velocity), and also at times at the binnacle compass to get an opinion as to the accuracy of the course about to be marked on the log-board. [Dead-Reckoning.] The ship's position at noon having been pricked off upon a chart, and the log duly written up as soon after noon as convenient, the remainder of the day calls for no further computations,—unless, as it occasionally happens, sights for the time were not procurable in the forenoon, and are taken at about 3 p.m, it being better to obtain them when the sun is about three hours from the meridian. Occasionally, a sailing navigator may see fit to try a lunar for his longitude, but this is entirely optional; or, perchance, in the evening an intelligent merchant captain may desire to verify his position by observation of a star, &c. So then as regards routine observation, the work of a sailing commander is very light. For even, if in addition to his daily routine he be approaching land, it entails no serious loss or labour to "lie-to" for a few hours till daylight.

But with a commander of a steamer, navigation is quite another thing; for in the first place, where a sailing commander deems it advisable not to close in with the land towards nightfall, because he depends upon the wind only, a change in which might suddenly place him on a lee shore; the steam commander would, as a matter of duty, take the shortest route, in whatever direction that might lie. It will then be evident that with a vessel of greater comparative speed, often using the more dangerous passage along a coast, her commander should be a man of increased nautical skill, and of special proficiency in navigation—the latter attainment being the more needed as he has scarcely the discretionary power to "lay-to," except under special circumstances. The stranding of a sailing ship may often be the result of sheer accident of wind or weather, while that of a steamer, which is locomotive, and can steer readily in any direction (in moderate weather), has been in too many instances found to have its cause in at least error in judgment.

To make the distinction between steam navigation and sailing navigation the plainer, we will suppose a case, as applicable to the following imaginary chart and track:—



Two vessels, the one sailing and the other steaming, are bound round the headland, *g*, of a continent. There are several outlying dangers near it, such as the island *b*, the rocks at *d*, the shoal at *e*, and in addition, rocky spits run off the points *c* and *g*. Suppose the two vessels to be in company at *a*, and each desirous of reaching the position *h*: the steamer would, as a matter of course, take the inner passage, in whatever direction the wind might blow, while if the wind were as indicated by the arrow in the diagram, the sailing ship could not venture, but must take the outer passage—and as a square-rigged ship can only sail within about six points of the wind, her track in working to windward or "tacking," would in this case between *a* and *h* be about thirty miles, while the steamer's would be about twelve. Now if we compare the two tracks it will be evident that the mind of the sailing master might well be free from care, except when approaching *e*, or the weather side of *f*; while during the whole passage, through a slight mistake or inattention on the part of the steam commander, he might lose the ship. Suppose farther, that just as the steamer reached her position near *d*, the weather became hazy or foggy, obscuring the land: the master of the sailing ship in the offing could without a care lay-to with the ship's head off the land, while the steamer must push on, if possible; because anchoring would inconveniently delay her passage. He would have in such case to prick off his actual position on his chart by hasty bearings, subject to the delay of correction for local attraction, &c., and indeed his work of navigation would form a perfect contrast to that of the ship-master outside. Farther investigation will even heighten the contrast, for in a passenger steamer, the commander finds the necessity of verifying his position as often as possible, by night as well as by day. He takes a larger number of observations, and needs every accomplishment which nautical astronomy offers him.

If then such disparity exist in the duties of certain maritime commanders, and if, moreover, no amended system of training have been yet perfected under authority, calculated to meet the increased intelligence called for by the exigence of steam navigation, the subject is worthy of most earnest attention.

An impression is gaining ground among experienced commanders themselves, that whereas other professions have their training based upon principles which are carefully explained to them, the navigator is consigned to work with formulæ of which he has no comprehension beyond their mere adaptation to his work. Trigonometry, plane and spherical, is the foundation of all his calculations, but neither are its principles explained in schools of navigation generally, nor is even the projection of its figures deemed important. In the Royal Naval School, and one or two others, this great defect has been of late attended to, and their example cannot, for the good of the community, be too soon followed by those who have had the training of nearly 50,000 of our population whose profession is that of the sea officer. That our sea captains are successful in their voyages as a general rule, depends on their perseverance and intelligence as a body: they complain that they owe little to science and teaching.

With regard to spheric trigonometry, circumstances already explained under Great-Circle-Sailing have strangely driven it from even the "Manual" of the Navigator. [Spherics; Spherograph.]

(Raper's *Treatise on Navigation*; Jean's Works on Trigonometry; *The Calculation and Projection of the Sphere*, Longman & Co.)

STEAM-VESSEL, a vessel moved by the power of a steam-engine acting upon paddle-wheels or other mechanism for propelling it through the water. Under Ship, Ship-building, &c., were explained the principles on which vessels are constructed; and under Steam, Steam-Engine, Propeller, &c., have been described the means of propulsion. Before entering upon the construction of steam-vessels, we give a brief notice of the rise and progress of the application of steam to navigation.

A curious claim has been brought forward on behalf of Blasco de Garay, a sea captain, who is stated to have exhibited in Spain, in 1543, an engine by which ships and vessels of the largest size could be propelled, even in a calm, without the aid of oars or sails. The documents relating to this claim, which, if correct, gives Spain the priority by a long period in experiments on steam navigation, were discovered in the royal archives at Simancas, and were published in 1826, by Thomas Gonzales, director of the archives.

Stuart, in his 'Anecdotes of Steam-Engines,' endeavours to establish something like a claim to the invention of steam navigation by the Marquess of Worcester. The author alludes to a little engine, or great model, which he had "already erected" at Lambeth; and among many other purposes to which his invention might be applied, states that it may be used "to draw or hale ships, boates, &c. up rivers against the streame; to draw carts, wagons, &c. as fast without cattel; to draw the plough without cattel, to the same despatch if need be," &c.

The project to be next alluded to is that of Papin, who proposed an apparatus somewhat like that subsequently patented in England by Jonathan Hulls. Those who have endeavoured to establish a claim to the invention of steam navigation on behalf of France, have pleaded Papin's suggestion in favour of their views; but none, so far as we know, have asserted that he put his scheme to the test of experiment.

On December 21, 1736, a patent was granted to Jonathan Hulls for a machine which may be designated a steam tug-boat; of which a full description was published in the following year, in a sensible pamphlet, entitled 'A Description and Draught of a new-invented Machine for carrying Vessels or Ships out of or into any Harbour, Port, or River, against Wind and Tide, or in a Calm.' Hulls proposed to place an atmospheric steam-engine in the tug-boat, and to communicate its power by means of ropes to the axis of a kind of paddle-wheel mounted in a frame-work projecting from the stern of the vessel. A contrivance is added for continuing the motion of the paddles by the descent of a counterbalance-weight, in the intervals between the strokes of the piston. To guard against the injury of the fans or paddles by the violence of the waves, Hulls proposed to lay pieces of timber so as to swim on each side of them. The objections likely to be brought against the scheme are anticipated and answered by the writer, who expresses his opinion that it would be found better to place the machine in a separate vessel than in the ship itself, because the machinery would be cumbersome in the ship, and, if in a separate vessel, it might lie at any port to be ready for use, &c.

The next circumstances which claim notice in the history of the invention of steam navigation afford the principal reasons for attributing, as some of their writers have done, the origin of the art to the French. In 1774, the Comte d'Auxiron, a French nobleman of scientific attainments, constructed a steam-boat, and tried it on the Seine, near Paris. It appears that the engine had not sufficient power to move the wheels efficiently, an error into which many of the early experimenters fell; and consequently the result was unsatisfactory, and the persons who had united to enable the Comte to construct the machine, abandoned the project. In the next year, 1775, the eldest of the ingenious brothers Perier, who had assisted in d'Auxiron's experiment, resumed the attempt, and placed a very imperfect engine, of about one-horse power, in a boat on the Seine, connecting the engine with two paddle-wheels. He also laboured under the disadvantage of having too little engine-power, and therefore failed to obtain any satisfactory result; his boat moving but slowly against the current of the Seine. Fortified by the favourable opinion of the Marquis Ducrest, who perceived the cause of his disappointment, "Perier did not," observes Stuart, "altogether abandon the subject; and in succeeding years he made a few attempts with other propelling mechanism instead of paddle wheels, which he thought were defective substitutes for oars, and which, in his view, occasioned his failure." He did not, however, accomplish anything important; nor did his attempts, according to the author just quoted, excite much attention in France, or any at all in England. In an Historical Notice on Steam-Engines, by M. Arago, in the French 'Annuaire' for 1837, it is stated, probably from inadvertence, that M. Perier was the *first* to actually construct a steam-vessel. From this paper we learn that trials were made on a larger scale, in 1778, at Baume-les-Dames, by the Marquis de Jouffroy, who, in 1781 or 1782, tried a boat of considerable dimensions upon the Saône, at Lyon. Several English authorities give the dimensions of this boat as 140 feet long and 15 feet broad; but Arago says it was 46 metres long and 4½ broad. Colden's 'Life of Fulton,' in an extract from the 'Journal des Débats' for March 28, 1816, states the dimensions to have been 130 feet long and 14 broad. The vessel had a single paddle-wheel on each side, and the machinery appears to have been constructed with some skill, although it was not sufficiently strong. The experiments of the Marquis were eventually stopped by the political disturbances of the country. After a long exile, he returned to his country about 1796, and found that M. des Blancs, a watchmaker of Trevoux, had obtained a patent for a steam-vessel, which, it has been supposed, was constructed chiefly on the information which he could collect respecting that of the Marquis. Jouffroy appealed to the government, but nothing important resulted from his doing so, or from the experiments of M. des Blancs, which, like those of Jouffroy, were made on the Saône. While M. des Blancs was engaged in his steam-boat project, Fulton, who was then in France, was also experimenting upon the same subject. It appears, indeed, that both tried the scheme of propelling by means of paddles or float-boards attached to an endless chain stretched over two wheels projecting from each side of the vessel. Fulton abandoned this plan, and adopted paddle-wheels in its stead; but during his experiments, M. des Blancs complained of his operations as an infringement upon his patent right, and remonstrated with Fulton upon the subject.

The narrative must now return a few years, in order to notice the attempts making in North America to solve the problem of propelling vessels by mechanical power. Without noticing mere vague suggestions of its possibility, of which some have been mentioned of earlier date, we find that two individuals named Fitch and Rumsey were early in the field as experimentalists. Stuart goes into their claims very minutely; but it may be briefly stated that as early as 1783 Fitch had succeeded in moving a boat on the Delaware by means of paddles (not paddle-wheels) set in motion by a steam-engine; and that in 1785 he presented a model and description of his apparatus to Congress. He was supported for some time by an association of wealthy persons, and was so sanguine as to the success of his project, as to send drawings and descriptions of his machinery to Messrs. Boulton and Watt, in order that they might procure an English patent for it. Nothing was accomplished by Fitch and his friends in England, and but little in America. It is worthy of notice that Fitch expressed his belief that the time would come when steam-power would be employed for crossing the Atlantic. Rumsey, the rival of Fitch, had exhibited a model of a contrivance for moving a boat, to General Washington, as early as 1784; but Fitch alleged that it was merely an apparatus for enabling a boat to stem the current of rapid rivers, by means of wheels, cranks, and poles; and that it had been tried some years before by another person on the Schuylkill, and had failed. In 1787, Rumsey made some short voyages on the Potomac, with a boat about fifty feet long, propelled by the re-action of a stream of water drawn in at the bow and forced out at the stern by means of a pump worked by a steam-engine. This boat moved, it is said, at the rate of three or four miles an hour, when loaded with three tons, in addition to the weight of her engine, which was about one-third of a ton. The boiler held only five gallons of water, and the whole machinery did not occupy more space than four barrels of flour. The fuel consumed was from four to six bushels of coals in twelve hours. Rumsey afterwards proposed applying the power of a steam-engine to long poles, which were to force the boat forward by reaching the bed of the river, when it had to move against a rapid current. Rumsey, as well as Fitch, was backed by a company; and their respective friends did not confine their rivalry to America, for the adherents of Rumsey addressed themselves to Boulton and Watt in opposition to the statements of Fitch. After all their conflicting pretensions, however, neither succeeded in the practical establishment of steam navigation. Rumsey came to England after the failure of his projects in America, and commenced a steam-boat on the same principle as that he had used on the Potomac, which was in some respects like the much older plan (1730) of Dr. John Allen. He died before the completion of this vessel; but it was finished by the persons associated with him, and was brought to trial in February, 1793. This steam-boat performed several times on the Thames, against wind and tide, and attained a speed of four miles an hour. This method of propelling a boat was subsequently tried by Mr. William Linaker, master-shipwright in Portsmouth dockyard, who obtained a patent for it in 1808. His experiments had, as appears by his papers, been commenced as early as 1793. Stuart states that a similar apparatus was tried on the Thames after Linaker's death, the engine used being on the principle of that invented by Savery.

While Fitch and Rumsey were making their experiments in America, other experiments were in progress in Scotland, which tended, more than any previous trials, to the useful application of steam to the purpose of propelling vessels. Of the highly interesting experiments made in 1788 and 1789, under the auspices of Patrick Miller, Esq., of Dalswinton, in Dumfriesshire, many accounts are extant, differing indeed very slightly from each other, yet tending, by the colouring given to minor details, to attribute different degrees of honour to the three individuals by whom they were carried out. It is not likely that this question will ever be thoroughly set at rest; for the degree in which each contributed to the success of the experiments will ever be estimated differently, according to the peculiar mode of judgment adopted by the inquirer. Without desiring to throw any slight upon those who differ from him, rather in his deductions than in the facts upon which they are based, our narrative will be condensed from that of Mr. Russell, who has evidently taken much pains to produce a satisfactory account of the whole course of proceedings.

After stating that it has been very usual to attribute the invention of steam navigation to Miller, and that two competitors have contested his claim, Mr. Russell observes, "We shall soon see that to no one of the three can the palm be awarded. The creation of the steam-ship appears to have been an achievement too gigantic for any single man. It was produced by one of those happy combinations in which individuals are but tools working out each his part in a great system, of the whole of which no single one may have comprehended all the workings." The persons who have contested the title of inventors of steam navigation, or rather, they for whom the title has been contested by others, are Patrick Miller, James Taylor, and William Symington; and, after a long and patient examination of their respective claims, and of the papers, published and unpublished, of the parties who advocate the cause of each, as well as of the personal testimony of such individuals as could throw light on the case, our author gives it as his conclusion that the art of steam navigation was the joint invention of the three. It will be seen from the history given above, that if the mere suggestion of applying a steam-engine to the propulsion of a vessel, or even the actual construction of a steam-boat, be considered sufficient to entitle a person to the name of inventor of steam navigation, that name belongs to some earlier projector, Hulls for instance, and not to any of the three individuals just mentioned; and if, on the other hand, the honour be due to those who produced the first successful steam-boat, it cannot be applied with propriety to any individual, seeing that the superiority of the boats of Miller, Taylor, and Symington was attributable to a happy union of talent and enterprise.

Mr. Miller, of Dalswinton, had been engaged in attempts for the improvement of naval architecture, proposing to build ships of much greater length than usual, in proportion to their breadth, and, in order to enable such narrow vessels to bear sail, to unite two or even three boats or hulls, side by side, so as to form a double or triple boat. He had also experimented upon the application of paddle-wheels, turned by a power within the vessel, instead of, or rather as auxiliary to, the force of the wind. Russell observes, that he does not find that Miller anywhere claimed absolute property in the invention of paddle-wheels, which, as has been already stated, had been often tried. Having thus prepared a form of vessel suitable for the purpose of steam navigation, and provided it with an apparatus for propelling it through the water, it only remained to apply the steam-engine itself. This, it appears, was done subsequently, in consequence of the suggestion of Mr. Taylor, who, in 1785, went to reside in Mr. Miller's family as tutor to his younger sons, and, in 1786 and 1787, frequently assisted in his experiments with paddle-wheel boats. In one of these, in the latter year, one of Miller's double boats, sixty feet long, propelled by two wheels, each of which was turned by two men, was matched against a Custom-house boat, which was reckoned a fast sailer; and on this occasion the want of a sufficient moving power to turn the wheels was sensibly felt. Both Miller and Taylor perceived this; but when the latter suggested the steam-engine, Mr. Miller, for a time, questioned its applicability. In 1787 he published an account of his experiments, in which he observed, after describing his paddle-wheels, "I have also reason to believe that the power of the steam-engine may be applied to work the wheels, so as to give them a quicker motion, and consequently to increase that of the ship. In the course of this summer I intend to make the experiment; and the result, if favourable, shall be communicated to the public." This project formed the subject of much conversation at Dalswinton in the summer of 1787, and was mentioned by Taylor to his intimate friend Symington, who was then engaged as a mining-engineer at the Wanlockhead lead-mines, but had devoted much attention to the improvement of the steam-engine, and had recently constructed a model of a steam-carriage [STEAM-CARRIAGES], in which he had provided simple means for converting the reciprocating motion of the pistons into a rotatory motion. Thus, while Miller had been preparing a proper vessel and propelling apparatus, and Taylor had been recommending the agent required to work it, Symington had been effecting those modifications in the structure of the engine which were necessary to adapt it to the purpose required. There is some reason, indeed, to believe that he had conceived the possibility of this particular application of the steam-engine; for, in a letter to Taylor, dated August 20, 1787, apparently in answer to one just received from him, Symington says, "I must make some remarks upon your summer's inventions, which, if once made to perform what their author gives them out for, will undoubtedly be one of the greatest wonders hitherto presented to the world, besides its being of considerable emolument to the projector. Great success to you, *although overturning my schemes*." In December of the same year the Dalswinton experimenters were in Edinburgh, where they met Symington, and, at the house of his patron, Gilbert Meason, Esq., saw his steam-carriage model. The result of this meeting was, that Symington, in conjunction with Miller and Taylor, constructed a small engine in the following summer; the castings being, by a curious coincidence, executed by a founder of the name of Watt. In October, 1788, this engine was placed in a small double pleasure-boat belonging to Mr. Miller, and was tried upon Dalswinton lake. The engine was placed on one side, the boiler on the other, and the paddle-wheel in the middle. With all the disadvantages of a first experiment, and with cylinders of only four inches diameter, the boat moved with a velocity of five miles an hour. After repeated satisfactory trials, the engine was removed from the boat, and kept for many years as a trophy in the library at Mr. Miller's.

Had the experiments of Miller and his fellow-labourers stopped here, it might have been conceived that their success was in some degree attributable to accidental circumstances. The result of a second experiment, in the following year, is sufficient to dispel any such idea. In 1789 an engine of about twelve-horse power (or twelve times the power of the first) was made by the same parties at the Carron works. This was mounted in the large double boat which had formerly run against the Custom-house boat at Leith. Except in size, this machine resembled the former model. The engine was commenced in June, and near the end of the year the boat was tried on the Forth and Clyde canal. Some difficulty was at first experienced from the weakness of the fastenings by which the float-boards or paddles were secured to the arms of the paddle-wheels; several of them being broken off by the severe strain to which the power of the engine subjected them. When this matter was set right, the boat performed very successfully, and attained a speed of nearly seven miles an hour, "being," observes Mr. Russell, "about as great a velocity as it has been found possible to obtain by steam-boats on canals, even at the present day." The vessel having been built for a different purpose, and being much too slight for permanent use as a steam-boat, or for taking out to sea, was, soon after the trial, dismantled. Mr. Miller, having thoroughly proved the practicability of the plan, and having expended a large fortune in his enlightened pursuits for the public benefit, relinquished the experiment, leaving its great results to be worked out by others. That he should have done so need excite no surprise, when the difficulties attending the introduction of any great improvement are considered. Taylor was still less likely to take any effective steps for carrying out the grand design; and Symington was not in a situation to do so immediately, although he was subsequently engaged in further experiments to that end.

Satisfactory as was the result of these experiments, they did not immediately lead to the introduction of steam navigation; and several other unsuccessful schemes were tried in this country and in North America before it was effected. One of these, that of Rumsey, the American, on the Thames, has been already mentioned. About this time Dr. Cartwright contrived a steam-barge, and explained it to Fulton. Some authorities state that it was shown to Fulton in 1793, when he was studying painting under West; but others date it a few years later, stating that he was introduced to Dr. Cartwright during his journey to Paris in 1796. However this might be, it is evident that Fulton's attention was directed to the subject about this time. Colden, his biographer, states that he made drawings of an apparatus for steam-navigation in 1793, and soon afterwards submitted them to Lord Stanhope. In 1795, Earl Stanhope himself made experiments with a steam-vessel propelled by duck-feet paddles placed under the quarters, like those recommended in 1759 by Genevois, a Swiss pastor. Notwithstanding the ingenious folding of the paddles, in order to diminish the resistance of the back-stroke, the apparatus required so much power that, with a powerful engine, he could not obtain a speed greater than three miles an hour.

In 1801 Symington commenced a satisfactory series of costly experiments on steam-navigation, under the auspices of Thomas, Lord Dundas. The object immediately aimed at was the introduction of tug-boats instead of horses for drawing boats upon canals. After several minor trials, one of the boats built on this occasion by Symington drew, on the Forth and Clyde canal, in 1802, two loaded vessels, each of seventy tons burden. On this occasion, it travelled with its load a distance of nineteen miles and a half in six hours, although there was so strong a wind ahead that no other vessels in the canal could move to windward on that day. The tug-boat was a rather short vessel, with a single paddle-wheel in the stern, impelled by a horizontal cylinder of twenty-two inches diameter and four feet stroke, working, by means of a connecting-rod, a crank on the axle of the wheel. The rudder was double, on account of the situation of the paddle-wheel, and it was moved by means of a tiller-wheel in the fore-part of the vessel. A complete model of this boat may be seen at the Royal Institution of London. In this case, though the object aimed at was fully attained, as far as the successful performance of the vessel could go, the project was abandoned, in consequence of an idea that the undulation of the water occasioned by the paddle-wheel would prove injurious to the banks of the canal. The speed attained by this steam-boat, when unimpeded by having any others to draw after it, was about six miles an hour.

While the experiments of Symington, under the patronage of Lord Dundas, did not lead to the immediate adoption of steam-vessels for commercial purposes, they probably tended, in no unimportant degree, to their subsequent profitable establishment in America and in Great Britain; for among the numerous individuals who inspected his vessel with interest were Fulton and Bell. It has been shown that projects for steam-navigation had been early tried in North America. After Fitch and Rumsey, the chancellor Livingstone attempted to build a steam-boat on the Hudson, and in 1797 he applied to the legislature of the State of New York for an exclusive privilege to navigate boats by a steam-engine. Though his project excited much ridicule, the privilege was granted in 1798, on condition that he should, within twelve months, produce a steam-vessel which should attain a mean rate of at least four miles an hour. This he failed to accomplish, although assisted, it is said, by an Englishman named Nesbit, and by Brunel (afterwards Sir Mark Isambard), and consequently his grant or patent became void. Shortly afterwards, being at Paris as minister from the United States, Livingstone conversed with Fulton on the subject of steam-boats, and intimated his intention of resuming the experiments on his return to America. Fulton then commenced, under his auspices, the experiments which have already been alluded to as exciting the jealousy of M. des Blancs. After several preliminary measures, Fulton and Livingstone completed a boat of considerable size on the Seine, near Paris, early in 1803; but, being too weak to bear the weight of her machinery, she broke through the middle, in a gale of wind during the night, and went to the bottom. To this discouraging accident Mr. Russell attributes one of the excellences of American steam-boats,—the strong and light framing by which, though slender, they are enabled to bear the weight and strain of their large and powerful engines. To remedy this evil, Fulton had to reconstruct his vessel almost entirely, after her shattered hull was raised; and in August of the same year he had her in trying order. This vessel was 66 feet long and 8 feet wide. The speed attained was much less than had been hoped for; but the result of the experiment was such as to induce the projectors to order an engine of Boulton and Watt, with a view to further trial in America. As the boat into which it was fitted was the first regularly established steam-packet, it will be noticed in the second part of our history; but before closing this narrative, allusion must be made to the proceedings of Fulton between the time of these French experiments and his successful enterprise on his return to America. During this time he visited England [FULTON, ROBERT, BIOG. DIV.]; and while here he introduced himself to Symington, from whom he asked for particular information respecting what he had done in steam navigation.

This brief sketch of what may be termed the preliminary history of steam navigation would be incomplete without referring to the experiments of John Stevens, of Hoboken, near New York, who was connected with some of the earliest attempts of Livingstone to introduce steam navigation in North America. Stuart describes a small boat, twenty-five feet long and five feet wide, impelled by a steam-engine with a cylinder of four inches and a half diameter and nine inches stroke, which he tried about New York in 1804. The boiler, which was only two feet long, fifteen inches wide, and twelve inches high, consisted of eighty-one tubes of an inch diameter. This little steam-boat had a velocity of about four miles an hour, or, for short distances, of seven or eight miles an hour. The subsequent vessels of Stevens and his son will be hereafter noticed. About the same time (1804) Oliver Evans, another early American improver of the steam-engine, constructed his "Orukter Amphibolos," or machine for removing mud from docks, with a steam-engine to work the buckets. It was a heavy flat-bottomed boat, thirty feet long and twelve feet broad. Evans constructed this machine at a distance of a mile and a half from the river Schuylkill, and exhibited his long-cherished project of steam locomotion on land by mounting it upon wheels, and connecting them with the engine. After doing this to his satisfaction, he fitted a paddle-wheel to the stern of the machine, and launched it on the river as a steam-boat.

It is not pretended that the above account embraces every project brought forward, or even every public experiment made respecting navigation by steam; but enough has been related to show that its possibility had long been contemplated, and that many persons had expended much time and money upon the scheme before a single steam-vessel was regularly used for the purposes of commerce. Upon the subsequent history of steam navigation it is needless to treat at length; but, before entering upon it, it may be well to state that besides the claims to the invention which have been put forth on behalf of Spain, France, England, Scotland, and North America, one has been made also for an Italian, named Serapino Serrati, in a work published at Florence in 1796, in which it is stated that Watt was the inventor of steam-engines in England in 1787, but that Serrati was "the first not only to conceive the design of a steam-boat, but also to place one upon the river Arno, which runs through Florence." Russell observes that he had no means of testing the truth of this statement, but that, like the narrative of Garay's performances, it may be either true or untrue, without affecting the history of steam navigation; since it is evident that our present system of steam navigation has been in no way derived from either of them.

Fulton returned to America towards the latter end of 1806, and immediately commenced building a steam-boat for use upon the Hudson. This vessel was built at New York, and was launched in the spring of 1807. The engines were mounted and ready for trial by August in that year, engineers from Soho assisting in the work, and when the vessel started, its success became immediately evident. Soon afterwards this vessel, which was named, from Livingstone's residence, the Clermont, made her first voyage from New York to Albany, a distance of about a hundred and forty-five miles; which distance it accomplished at the rate of about five miles an hour.

Satisfactory as was the performance of the Clermont, she did not, owing to the want of proper proportion in the wheels, attain so great a speed as Fulton had anticipated. The dimensions of the boat, which was of a hundred and sixty tons burden, were one hundred and thirty-three feet long, eighteen feet wide, and seven feet deep. Her cylinder was two feet in diameter, and four feet stroke; and the paddle-wheels were fifteen feet in diameter, with paddles four feet long, dipping two feet into the water. These dimensions probably refer to the improved paddle-wheels used subsequent to the first trial, those originally used being too large, so that they dipped too deep into the water. The wheels were of cast iron, and had no support beyond the sides of the vessel, and consequently some trouble was occasioned by their frequent breakage in the earlier experiments. Until his death in 1815, Fulton continued to be actively engaged in building steam-vessels, and at that time he had just completed a large steam-frigate or floating battery, supported by two hulls, with a canal fifteen feet wide between them, in which the paddle-wheel worked. So highly were his services then appreciated, that besides other testimonies of respect, the members of both houses of the legislature wore mourning on occasion of his death.

Fulton had scarcely launched the Clermont before a rival appeared. Stevens of Hoboken had a steam-vessel ready for trial in a few weeks after the triumph of Fulton; but, as the monopoly of steam navigation in the state of New York was secured to Livingstone and Fulton, he could not employ it upon the Hudson, and therefore took it round by sea to the Delaware, thus becoming the first (unless the case of Garay be an exception) to venture to sea with a steam-vessel. To R. L. Stevens, his son, American steam navigation is deeply indebted. He, according to Russell, improved the form of the American vessels, by substituting a very long proportion, with a fine entrance and a fine run, for the full round bows and sterns of Fulton, whose boats were, he says, mere boxes sharpened a little at both ends, which drove before them so large a heap of water as to limit their speed to about nine miles an hour. The improvements of Stevens enabled him to rise to a velocity of thirteen miles an hour. He also adopted a different form of engine from that of Fulton; using cylinders of very long stroke, with upright guides, instead of the old parallel motion, to ensure the accurate motion of the piston, and placing the working beam above the deck, instead of altering the usual arrangement of the machinery in order to keep it below the deck, as done in Fulton's engines and in those commonly used in British steam-vessels.

The practical application of steam navigation in Scotland, though attributable to the experiments of Miller, Taylor, and Symington, at least as distinctly as were the operations of Fulton upon the rivers of North America, did not take place till a few years later, and was in some degree suggested by them. Henry Bell, of Helensburgh, on the Clyde, the individual by whom steam-vessels were first used in Britain for commercial purposes, had been well acquainted with the experiments at Dalswinton and on the Forth and Clyde canal; but he did not take any step for carrying into effect the important scheme of which they proved the practicability, until the proceedings of Fulton, combined with peculiar circumstances in his own case, urged him to do so. Owing to some misapprehension, it was erroneously stated in the Fifth Report of the Select Committee on the Roads from London to Holyhead, in 1822, that Bell went over to America to assist Fulton in establishing steam-boats in that country. In the minute and interesting narrative of Russell, who, from residing in the neighbourhood, had peculiar facilities for obtaining correct information respecting the history of steam navigation upon the Clyde, it is stated that Bell was a house-carpenter in Glasgow for many years, and was rather fond of what are called *schemes*. In the year 1808 he engaged in an undertaking somewhat of this character, by becoming proprietor of an establishment of the nature of an hotel, or bath-house, at Helensburgh, a watering-place on the Clyde, opposite to Greenock. To increase the facilities for reaching this place, and thereby to induce a larger influx of visitors from Glasgow, Bell endeavoured to introduce passage-boats moved by paddles impelled by manual labour; but his experiments failed, and at length he determined upon the construction of a steam-boat to meet the difficulty. Thus his connection with an undertaking of very different character, combined with his correspondence with Fulton, led him to take this important step.

The Comet, built by Bell in 1811, was a vessel of forty feet keel, and ten and a half feet beam; of about twenty-five tons burden, and three-horse power. This vessel began to run regularly between Glasgow and Helensburgh, in January, 1812, and continued to ply successfully during the following summer; her rate of motion was about five miles an hour. The second steam-boat established on the Clyde, the Elizabeth, was commenced as early as March, 1812, and was ready for use about twelve months after. She was the property of Mr. Hutchison, a brewer; but she was built under the direction of an engineer named Thomson, who had been engaged in some of Bell's first experiments. She was of longer proportion than the Comet, being fifty-eight feet long aloft, fifty-one feet keel, twelve feet beam, and five feet deep; and her proportion of power to tonnage was much better, her burden being about thirty-three tons, and her engine of about ten-horse power. The Elizabeth performed the passage of twenty-seven miles, between Glasgow and Greenock, twice a day; and, according to her owner's account, made the voyage in something less than four hours, with a hundred passengers on board, and, in favourable circumstances, in two hours and three-quarters. She accomplished, it would appear from the same statement, a distance of eighty-one miles in one day, at an average rate of nine miles an hour.

Stuart relates that while Bell was engaged in establishing his steamers on the Clyde, a person named Dawson was making similar experiments in Ireland; and that he had, according to his own account, built a steam-boat of fifty tons burden, worked by a high-pressure steam-engine, as early as 1811; which, by one of those singular coincidences frequently met with in the history of inventions, he named the Comet. In 1813, it is added, Dawson established a steam-packet on the Thames, to ply between Gravesend and London, "which was the first that did so for public accommodation, although Mr. Lawrence of Bristol, who introduced a steam-boat on the Severn, soon after the successful operations on the Clyde, had her carried to London (through the canals) to ply on the Thames; but from the opposition of the watermen to the innovation, he was in the end obliged to take her to her first station." If this be correct, the Gravesend steam-packet alluded to must have been overlooked by the author of a pamphlet published in 1831, entitled 'An Account of the Origin of Steam-boats in Spain, Great Britain, and America; and of their Introduction and Employment upon the river Thames, between London and Gravesend, to the present time;' by R. P. Cruden, of Milton by Gravesend, who repeats the statement in his 'History of Gravesend,' (8vo, 1843,) p. 484. He states that the first steam-boat which plied between London and Gravesend was the Margery, of seventy tons burden, and fourteen-horse power; a vessel originally used on the Clyde, where she was built in 1813, by Messrs. Wood of Port-Glasgow, the builders of the Comet and the Elizabeth. She was, it is stated, brought to London from Leith early in 1815, and on the 23rd of January in that year she began to ply between London and Gravesend. This vessel was, in the following year, removed to France, for use upon the Seine; and that tried on the Thames by Dawson was, according to Stuart, sent to Spain, to ply between Seville and San Lucar. Cruden states that the Richmond packet had been employed between London and Richmond in the year preceding the use of the Margery on the Gravesend station.

Among the enterprising individuals by whose exertions steam-boats were established upon the Thames, the name of George Dodd deserves a prominent place, although his history is a melancholy instance of the poverty which often attends the most ingenious inventors. He was, it would appear, the first to undertake a considerable voyage by sea in a steam-vessel. The boat with which this voyage was accomplished was built on the Clyde by Messrs. Wood, and was launched in 1813, under the name of the Glasgow; but was subsequently altered, and called the Thames. She was of seventy-four or seventy-five tons burden, and about fourteen or sixteen horse-power, with paddle-wheels nine feet in diameter. Dodd brought her round to the Thames by steam and sails, experiencing some very rough weather on the way, especially in the Irish Sea. A detailed account of the voyage was published in the 'Journal des Mines' for September, 1815, and subsequently at the end of Dodd's work on steam-boats. It is needless to follow minutely the extension of steam navigation in the British dominions and elsewhere subsequent to the success of Bell and his immediate followers. Bell himself said, "I will venture to affirm that history does not afford an instance of such rapid improvement in commerce and civilisation as that which will be effected by steam-vessels;" and probably there are few at the present time who would not fully acknowledge the truth of his prediction, but it may be interesting to give, from Dodd, an enumeration of the principal steam-vessels in use in Great Britain and Ireland at the date of his work (1818). He states that there were then eighteen steam-boats on the Clyde, two at Dundee, two on the Tay, two on the Trent, two on the Tyne, four on the Humber, two on the Mersey, three on the Yare, one on the Avon, one on the Severn, one on the Orwell, six on the Forth, two at Cork, and two intended to navigate from Dublin to Holyhead. In another part of his work he describes the vessels then in use upon the Thames, of which two, the Richmond and the London, plied between London, Richmond, and Twickenham, and had, he says, carried not less than ten thousand passengers within the last four months. These were built under Dodd's superintendence; and in consequence of having to pass under the bridges, they were made with an apparatus of his invention for lowering their chimneys. These boats experienced much but ineffectual opposition from the watermen, who deemed their use an invasion of their rights. A third steam-vessel designed by Dodd, the Sons of Commerce, intended for use between London and Gravesend, had been used, in the season preceding the publication of his work, between London and Margate, and had once performed the journey, about eighty-eight miles, in seven hours and thirty-five minutes. Her speed, when unassisted by wind or tide, was ten miles an hour. Another boat, the Majestic, plied between London and Margate in 1816. This vessel had been to Calais, and had often towed vessels of seven hundred tons burden down the river. The Regent, one of the early Thames steamers, was accidentally burnt off Whitstable, in July, 1817. Besides these, Dodd mentions the Caledonia, with two engines of fourteen-horse power, which had been from Margate to Flushing, and also on the Rhine; the Eagle, which had a single paddle-wheel in the centre, and failed, he argues, for want of room for the escape of the water agitated by the paddles; the Hope, a small vessel, built at Bristol, which proved a failure; and the Thames, the vessel which Dodd himself brought from the Clyde. In addition to British steam-vessels, it is stated that there were at that time steam-packets and steam luggage-vessels used in Russia, the Netherlands, France, and Spain; and that one was building in the East Indies. In order to give an approximate statement of the progress of steam navigation in the United States about the same period, a few facts may be quoted from the evidence of Seth Hunt, Esq., formerly commandant of Upper Louisiana, before the select committee of the House of Commons appointed in 1817 to consider the means of preventing the mischief of explosion on board steam-boats. This gentleman stated that there were then ten steam-vessels running between New York and Albany, two between New York and the State of Connecticut, and four or five to New Jersey, besides the ferry-boats, of which there were four. On the river Delaware there were also a number of boats, which plied between Philadelphia and Trenton in New Jersey; and others between Philadelphia and Newcastle, and Philadelphia and Wilmington, besides ferry-boats. Some of these were worked with high-pressure engines. There were steam-boats from Baltimore to Norfolk, which passed a part of the Chesapeak, several miles in width; and steam-vessels had been to New London, which is still more exposed; and also up to New Hertford. The Powhatan steam-boat, which was built at New York, had been exposed to a severe gale of wind in the open ocean for three days, after which it arrived at Norfolk, and thence proceeded up the James river to Richmond. The largest steam-boats in America were those upon the Mississippi, plying between New Orleans and Natchez. These vessels, the Etna and Vesuvius, were of four hundred and fifty tons burden, and carried two hundred and eighty tons of merchandise, one hundred passengers, and seven hundred bales of cotton.

The introduction of steam-packets upon the open sea was a favourite object with Dodd. He observes particularly the great importance of their establishment between Dublin and Holyhead, as the intercourse by sailing packets was liable to great delays. They were sometimes, it is stated, more than seventy-six hours at sea, although the distance is only about sixty miles. The use of steam-vessels upon this station was advocated for several years before they were regularly established; and Dodd had, on behalf of himself and friends, offered to bear the expense of two packets for making the experiment, provided the Post-office authorities would guarantee to him the conveyance of the mails, in the event of those packets fully answering his representations; but his offer was not accepted. It has been shown that some sea-voyages were performed at an earlier date; but the regular establishment of ocean steam navigation may be considered to have commenced with the Rob Roy, a steamer of about thirty-horse power and ninety tons burden, which commenced running in 1818 between Greenock and Belfast. This vessel was established by Mr. David Napier, who, says Russell, from the year 1818 until about 1830, "effected more for the improvement of steam navigation than any other man." This gentleman must be distinguished from his cousin, Mr. Robert Napier, of Glasgow, who is also honourably known for improvements of the same kind, but of a somewhat later date. David Napier, according to the interesting narrative of the progress of steam navigation in Britain, given by the above-mentioned writer, ventured at once to establish regular communication between Britain and the neighbouring countries, Ireland and France, by steam-vessels plying even during the stormy months of winter; though, previous to the time of his improvements, such vessels had scarcely ever ventured to sea except in fine weather. In order to make himself well acquainted with the difficulties to be overcome, he took passage, at the worst season of the year, in one of the sailing vessels which formerly plied between Glasgow and Belfast, and which often required a week to perform a journey that is now done by steam in nine hours. After anxiously watching the effect of the waves when the vessel was tossed in a storm, and satisfying himself that there was no insuperable difficulty, he retired contentedly to his cabin, leaving the captain of the vessel puzzled at his strange curiosity respecting the effect of rough weather. He subsequently tried experiments upon the best form of hull for getting through the water with the minimum of resistance; and these led him to adopt a fine wedge-like form for the fore part of his vessels, instead of the round full bow common in those propelled by sails. The Rob Roy, after plying two winters between Greenock and Belfast, was removed from that line, and employed as a packet between Dover and Calais. In 1819 he employed the Messrs. Wood to build the Talbot, of one hundred and fifty tons burden, into which he fitted two engines of thirty horse-power each. This fine vessel, the most perfect of her time in all respects, plied between Holyhead and Dublin; and she was soon followed, on the same line, by another excellent vessel, called the Ivanhoe. In 1821 steam-vessels were regularly established as Post-office packets on that important station. They had been intended merely as auxiliaries to the sailing packets; but they soon superseded them. From the evidence given before the Holyhead Roads Committee in 1822, it appears that even then the intercourse between the two countries had been reduced almost to a certainty; and that while, in the year preceding their adoption, exactly one hundred mails arrived in London after the proper time, there were only twenty-two cases of delay in the first nine months in which the steam-packets were used, although this period included the winter season, during the early part of which the weather was worse than had been known for more than sixty years. The vessels which were built expressly for this purpose were strengthened by diagonal framing upon the plan of Sir Robert Seppings.

The next important stage may be considered to be the building of the "Great Western" at Bristol in 1838, a larger steamer than had then been built, being nearly 1400 tons; and the first voyage by steam across the Atlantic. The tonnage of the Great Western equalled that of the largest sailing merchant ships which had been constructed. She left Bristol, and entered New York harbour under full steam in the extraordinary period of 15 days having on board a surplus of 148 tons of coal. It is true that the Sirius, a smaller steamer, had sailed from Cork before the Great Western left England, and had arrived in safety at New York just before her; but there was this important difference between the two voyages, the Sirius had performed much of her's under sail, while the Great Western had been propelled by steam only. Fourteen years later a large ship called the Australian, built of iron, on the Clyde, left Plymouth (June, 1852) for Melbourne touching for coals at St. Vincent, St. Helena, and the Cape, and anchored safely in King George's Sound, West Australia, on the 20th of August, having performed the whole voyage (including stoppages for fuel) in 76 days. This was the first attempt to reach Australia by steam, and led to the construction of such ships as the celebrated Great Britain, the ill-fated Royal Charter, and other ships of greater perfection. In 1854 a fine American paddle-wheel ship called the Golden Age, astonished our Liverpool builders by her size and power, and gave the first intimation of a change in form likely to become general among ocean steamers. The total omission of a bowsprit and the relief afforded the fore part of the ship as a floating bulk, by the removal of the usual dead wood about the stem and figure-head, was a change deduced from scientific experiments becoming more and more followed. The Golden Age had taken in at one port alone (Tahiti) about 1200 tons of coal, an enormous weight, double that which only 15 years before had been the supply to the Great Western.

Another memorable event in the history of ocean steamers was the voyage of the steam screw ship Argo of 1850 tons, which at about this period circumnavigated the globe, the duration of her actual voyage being only 124 days.

Since this period a number of gigantic ocean steamers have been built for the companies known as the Peninsular and Oriental, the Royal West India Mail, the Cunard, &c. Among these the Persia is the largest of paddle steamers. Some of these magnificent vessels are of about 3500 tons, fitted with exquisite taste and elegance. But the greatest triumph of naval architecture, and the most extraordinary as to size is the Great Eastern, built in 1859 by Mr. John Scott Russell, on the Thames, from the joint designs of himself and Mr. Brunel. This stupendous vessel is of the length of 691 feet on deck, has a breadth of 83 feet and depth of 58 feet, having a gross registered tonnage of 18,914, but said to be capable of carrying 25,000 tons!

The most prominent events in the history of steam vessels having been thus mentioned, a few general remarks will show the actual position of this important subject.

It is, perhaps, impossible to over-estimate the importance of the building of the Great Eastern as an iron ship. In many prior cases steam ships had been saved from foundering by being built of metal. The writer was one who encountered the fearful hurricane of September, 1853, in the Ravensbourne in the North Sea, and long previous experience of the sea enables him to declare that no vessel built of wood could have braved such a prolonged tempest with impunity, inasmuch as the twistings of the frame of the ship must have started trenails and butt ends, to her inevitable destruction, and that of the crew and passengers. The well-known instance of the Great Britain lying a whole winter on shore in Dundrum Bay, exposed to the action of heavy surf, is a powerful fact in favour of iron ships. The introduction of water-tight compartments has also long been a consideration. Steam vessels are greatly strengthened by means of these water-tight bulkheads or transverse partitions in the hull, the general adoption of which, more than any other improvement, increases the safety of steam navigation. In a vessel of the ordinary construction a small local injury from striking upon a rock, from collision, or from any other cause, may occasion the sinking of the vessel, because the water has free access to every part of it. Fire also, wherever it may commence, is pretty sure to spread through the whole length of the boat. The adoption of water-tight bulkheads, to confine the effect of an accident to the particular division of the vessel in which it originates, was suggested by Dodd as early as 1818. He mentions them in p. 220 of the treatise which has been alluded to in the former part of this article, proposing to use them between the engine-room and the cabins; and he states that he intended to introduce them in two boats which he was then building. Whether he did so or not we are unaware; but the adoption of this excellent precautionary apparatus appears to be due to Mr. C. W. Williams, managing director of the City of Dublin Steam-packet Company. A minute description of his bulkheads, and a very satisfactory statement respecting their importance and their efficiency, are given in a communication from that gentleman to the commissioners on steam-vessel accidents in 1839, which is printed in the appendix to their report. He therein states that he first applied water-tight bulkheads in an iron steamer called the Garryowen.

Many instances have occurred in which water-tight bulkheads have saved life and cargo. One of our largest paddle-steamers, in March, 1857, struck an iceberg with such force as would have shivered a wooden ship (or a badly-built iron one) to pieces. As it was, extensive damage to the forefoot caused the fore compartment to fill with water, but so little did it affect the duration of the voyage, that the passengers were unconscious of anything beyond the concussion; nor did the public ever hear of anything beyond the shock, as the next voyage was performed without thorough repair.

In the Great Eastern, not only has a complete system of water-tight compartments been carefully arranged, but these have been longitudinally crossed by fore and aft bulkheads, in such a manner that neither one nor several perforations of her bottom would disable her; and, in addition to these, a considerable portion of her is doubled, so that the outer skin of plates, separated above two feet from a complete water-tight inner bottom, renders her not only the safest, but the strongest ship in the world; for these two separate bottoms are so broad and stayed, and the whole is so contrived, that her construction may be called cellular or tubular. She is a ship perfect on Scott Russell's wave principle [Ship-Building], with 120 feet of midship portion, the sides of which are perfectly parallel; but with this portion the lines of the stem and stern portions are so gracefully combined, that her form is considered the finest afloat.

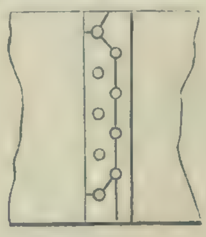
It is difficult for non-nautical persons to comprehend the disparity in size between the Great Eastern and all that preceded her. The best mode of comparing her with other vessels is by noticing that the engine-room of the Great Eastern occupies a cubic space of 5571 tons. Now the Duke of Wellington, a splendid three-decker of 121 guns, is of 3826 tons. Not only, therefore, would the Duke of Wellington stow in the Great Eastern's engine-room, but there would remain surplus space for one of our fine frigates—say, for example, the Orestes, of 1702 tons; and as regards the remaining portions of the Great Eastern, she could, in addition, stow away H.M. ships Waterloo, of 91 guns, with the Goliath, Meanee, and Vanguard, each of 80 guns. And again, whereas the Great Western carried 600 tons of coal as fuel, the Himalaya 1000 tons, and the Golden Age 1200 tons, the Great Eastern carries 10,000 tons. And further, the Great Eastern, when immersed to her load water-line, requires 95 tons to be placed on board her in order to sink her one inch deeper, while the Persia requires only 30.

The great inducement for increasing the size of merchant ships, and which has led in particular to the building of the Great Eastern, is that large ships alone are fit to carry fuel sufficient for a long voyage; coal, when supplied at intermediate stations, being often much augmented, perhaps quadrupled, in cost.

It would be impossible to enter upon the merits of various kinds of vessels now afloat, a large number of which are either fitted with screw or paddle; but we remark that so many vessels are now built of iron, that it has been thought necessary by the committee of Lloyd's, London, to keep a check upon their mode of construction, in defence of the interests of underwriters, by instituting a few regulations as to the dimensions of the framing, plates, &c., of iron vessels. As an example, no vessel of 3000 tons, built of iron, is allowed to have a keel, stem, or stern-post less than 12 inches by 3½. The upright ribs, which correspond with "timbers" in the wooden ships, must be 18 inches apart, and be formed of angle iron of 6½ in. × 4 × ¹¹⁄₁₆. The thickness of plates for garboard strakes to stand as A 1 for six years, ¹⁵⁄₁₆ in.; for nine years, 1 in.; for twelve years, 1¹⁄₁₆ in. Plates between garboard strakes and bilge and the sheer-strakes, for six years, ¹¹⁄₁₆ in.; for nine years, ¹³⁄₁₆ in.; and for twelve years, 1 in. Thickness of plates for beams, ⅝ in.; for bulkheads, ⁹⁄₁₆ in. Angle iron for beam and stringers, or keelsons, 6½ in. × 5½ × ⅝. Thickness of wood for upper decks, &c., 4 in.; while even the sizes of the rivets are determined in proportion to the thickness of plates: as an example, ⅜ in. plates must have rivets at least ⁵⁄₁₆ in. in diameter; ⅝ in. plates, ½ in.; ⅞ in. plates, ¹¹⁄₁₆ in.; and 1 in. plates, ⅞ in. thick. So important an item of the building of an iron ship has the use of rivets been found to be, that very elaborate experiments were in 1857 undertaken by the committee of Lloyds, under the direction of their surveyor, Mr. Mumford, to discover a system of joining iron plates by iron rivets which, while they secured sufficient strength, had no tendency to facilitate the rusting of the plates at the rivet-holes.

A piece of iron plate ⅞ in. thick was subjected to a strain in the hydraulic press, and its breaking strain was found to be about 65 tons to the foot breadth of the plate. Riveted plates were afterwards subjected to strain in the same machine, each rivet being ⅝ in. in diameter, and the rivets were in each plate varied in position. We give the following as illustrations; the whole particulars of each experiment may be seen in the surveyor's report, as published in full in the 'Transactions of the Institute of Naval Architects in 1860':—

Rivets 4 diameters apart.



Lapped plates.
Plate 13¼ in. broad.
Breaking strain 42 tons.
Strain upon 12 inches 38·03 tons.
Fracture through the countersunk plate.

Solid plate.

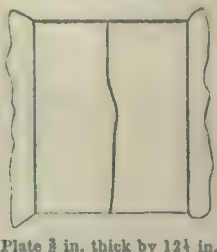


Plate ⅜ in. thick by 12½ in. broad.
Breaking strain 67 tons.
Strain upon 12 inches 65·63 tons.

If we now turn our attention to the arsenals of war, a like series of novelties in steam-shipping awaits us. The question of iron armour for our wooden ships, for ships built entirely of iron, or built partly of iron and partly of wood, or of iron entirely with heavy plate armour, is at the present time an exciting subject. Under the presidency of Sir John Pakington, the Institute of Naval Architects has already considered the question of a screw fleet with advantage; and the veteran Sir Howard Douglas, the Earl of Hardwicke, Captain E. P. Halsted, R.N., &c., have entered upon the subject with characteristic earnestness and professional zeal. To detail what is doing would be premature. It is enough to say that the question of steam-ships was never one of such importance to England as at present. Much might be said of an experiment made by France in building ships coated with heavy armour, like La Gloire. Opinions, however, are so conflicting on various vital points, that, having touched briefly the prominent outlines of the subject, it must be left to the future to chronicle the ultimate success or failure of such experiments.

Two noble vessels called the Warrior and the Black Prince, the one built recently on the Thames and the other on the Clyde, will bear prominently on the future history of steam shipping; a brief description, therefore, of one of these will be interesting, and the more so as a sort of rivalry between ourselves and another country exists in the question which is likely to influence very materially the nature of future naval warfare.

And first, the La Gloire is a fine wooden ship, having a length of 252 feet between perpendiculars, her breadth is 55 feet, and her draft at load water 27½ feet. She is steamer-rigged, having square sails only on her foremast. Her masts are small in proportion to the hull. It is supposed that her ports are only between 6 and 7 feet above water, in consequence of the weight of her defensive armour, which consists of plates of iron about 2 feet wide and 4½ inches thick, extending from stem to stern, and for a distance below water. Her horse-power is supposed to be 900, with screw propeller, and she carries 34 fifty-four pounders on her main deck, and 2 screened heavy shell guns forward. Her ports are 11¼ feet apart on the main deck, a formidable arrangement as compared with every ship that preceded her. But the Warrior is a greatly superior ship, as the following dimensions will prove. (The Black Prince is of the same size and build as the Warrior.)

The length of the Warrior is 380 feet between perpendiculars (420 feet over all), she is of 58 feet beam, 41½ feet depth from spar-deck to keel, 26 feet draft of water, and of the burden of 6177 tons, builder's measurement; fitted with screw propeller, and her engines, constructed by Penn and Sons, are of 1250 horse-power. She is built of iron, but her great peculiarity is that 205 feet of her length is protected by 4½-inch plates of solid iron, backed with two layers of teak timber, one of 10 inches next the armour, and another within that of 8 inches. Her armour extends to 9 feet below load-water line; and at the extremities of the armour-clad portion of her hull, and quite across the ends of the ship at those parts, iron bulkheads of strength equal to the sides (being 4½-inch iron backed with 18 inches teak timber), protect the engines and stores from shots which might enter obliquely from head or stern; and this inclosed space is divided into six water-tight compartments, her two boilers being each in its own separate compartment. In addition to this arrangement inner bulkheads extend all round the protected portion of her hull, leaving passages 3½ feet wide, so that any leakage-water runs below, and this affords room for necessary repairs if injured by shot, &c. Her main deck-ports are about 8½ feet above water (at load-water line), while her ports are 15¼ feet apart; thus ample space is given for working her guns, and for warlike operations. With the spars and sails of an 80-gun ship (but barque-rigged, having no crossjack yard), she will be immensely superior to the La Gloire.

The Warrior is nominally a 36-gun ship, but her guns will be 68-pounders, 95 cwt., for the main deck, 10 Armstrong (70-pounders) on the spar-deck, and 2 pivot 100-pounders (Armstrong's also), one at each end—in all 48 guns; and the number can easily be increased.

As a comparison, the Warrior's superiority to the La Gloire may be thus briefly stated:—

Ports much higher out of the water, therefore could fight her guns in bad weather when La Gloire could not open her ports.
Her deck is much higher, to facilitate boarding.
Has more space in which to work her guns.
Draws 18 inches less water than La Gloire.
Is less dependent on steam, being nearly full rigged.
Has greater speed, perhaps of 2 knots per hour.
Has heavier armament.
Besides having very superior accommodation for her officers and crew.

In closing this important detail it should be remarked, that early in 1859 Sir John Pakington, the first lord of the Admiralty, invited the naval architects from the coast to furnish plans for a mail-clad ship, and although numerous plans were forwarded (from Mr. Scott Russell, Mr. Samuda, Mr. Laird, Mr. Napier, &c.), the design adopted originated entirely in the office of the late Controller of the Navy, Sir Baldwin Walker, it being conceived by the Admiralty that such design contained the average proportions and qualifications of all the others.

The last suggestion as to steam vessels for war purposes is that by Captain Cowper P. Coles, R.N., who proposes certain sloping armour plates which shall throw off shot; and also certain modifications in the mode of arming men-of-war so constructed; inasmuch as he would have only one row of guns on the upper deck placed amidships, but placed on revolving, powerfully screened platforms. His highly ingenious proposals have already been well received by the Admiralty, and experiments on a ship fitted by him have been ordered, and will probably commence in a few months.

The following outline sketches, drawn accurately to a scale of 240 feet to an inch, give an illustration of the relative sizes of the Great Eastern, H. M. S. Duke of Wellington, the Warrior, La Gloire, the Himalaya, and the Great Britain, some of the most noted among English steam vessels.

Great Eastern, 691 feet.

H.M.S. Duke of Wellington, 121 guns, 241 feet.

H.M.S. Warrior, 380 feet.

La Gloire, 253 feet.

Himalaya, 341 feet.

Great Britain, 300 feet.

STEARANILIDE. [STEARIC ACID.]
STEARENE. [STEARIC ACID.]

STEARIC ACID ($HO,C_{36}H_{35}O_3$). This body is the most abundant constituent in all solid fatty substances. It exists in them in the state of *stearin*, a combination of stearic acid with the basis of GLYCERIN. The relation which stearic acid bears to other acids, that occur in fats and oils, will be readily seen on perusing the article on FATTY ACIDS. Stearic acid is sometimes met with under the name of *bassic acid* and *stearophanic acid*, and under the name of *anamirtic acid* occurs in the seeds of the *anamirta cocculus*.

Stearin is, for experimental purposes, generally prepared from mutton suet, from a solution of which in hot ether it crystallises out on cooling. By one or two recrystallisations it is perfectly purified. Thus prepared stearin forms white, pearly, lamellar crystals. When quite dry it is not greasy to the touch, and is easily pulverised. It melts when heated to about 144° Fahr., but by repeated fusions becomes more and more dense, and requires an increased temperature for its liquefaction. It is almost insoluble in water and only slightly soluble in cold alcohol or ether. Seven times its weight of boiling alcohol dissolves it, and less than that proportion of hot ether. By destructive distillation it yields oily and fatty hydrocarbons, acetic acid, acrolein, margaric acid, &c. By heating stearic acid with glycerin in closed vessels Berthelot succeeded in obtaining artificial stearins, containing one, two, or three equivalents of stearic acid united with glycerin. [GLYCERIN, *Monostearin*, *Distearin*, *Tristearin*.]

Stearic acid. Obtained by saponifying stearin with caustic potash and then precipitating the stearic acid by the addition of hydrochloric or tartaric acid to the hot solution of the resulting soap. It may be purified by washing with cold alcohol and recrystallising from hot alcohol. It may also be prepared directly from mutton suet by saponifying and decomposing, as above described, and then submitting the product to strong pressure; the greater part of the oleic acid is in this way removed and the remaining stearic acid obtained pure after one or two crystallisations.

Stearic acid crystallises from hot ether in transparent, colourless, lamellæ, having a rhombic outline. Its fusing point is about 167° Fahr.; but it does not resolidify until the temperature falls to about 158° Fahr. At higher temperatures it volatilises and is partially decomposed. It is insoluble in water; its alcoholic solution reddens litmus paper; it slightly decomposes carbonates in the cold, but completely on being boiled with them. A mixture of stearic and palmitic acids melts at a lower temperature than either acid does alone; thirty parts of the former and seventy of the latter fuse nearly 20 degrees lower than the mean melting point of the two. Chlorine and bromine act upon stearic acid, especially when they are heated together, giving rise to chlor- and brom- derivatives. Such a body is chlorostearic acid, containing $HO,C_{36}H_{25}Cl_{10}O_3$. Nitric acid oxidises it to suberic, pimelic, adipic, succinic, capric, œnanthylic, caproic, and other acids. Anhydrous phosphoric acid removes from stearic acid the elements of two equivalents of water, and leaves a brittle, obscurely-crystalline mass, having the composition ($C_{36}H_{34}O_2$). Perchloride of phosphorus also acts energetically upon stearic acid. A mixture of stearic acid and glycerin maintained at 212° Fahr., and saturated with hydrochloric acid gives rise to *stearochlorhydrin*, a crystalline body containing ($C_{42}H_{41}ClO_6$).

Stearone, *stearene*, or *margarone*, is a colourless crystalline body produced on distilling stearic acid with one fourth its weight of quick lime. It fuses at 171° Fahr. and resolidifies at 162° Fahr. Its composition has not been satisfactorily determined.

Stearates are combinations of stearic acid with bases, and the compounds, like those of the other FATTY ACIDS, are termed *soaps*. Stearates are mostly fusible and decompose when strongly heated. Those of the alkalies are readily formed on heating stearin with the alkali, as in the ordinary method of making soap. From the alkaline stearates other stearates may be formed by precipitation with a soluble salt of the metal whose stearate is required; the alkaline stearates being soluble in water, the stearates of other metallic oxides being insoluble. The *neutral stearate of potash* contains ($KO,C_{36}H_{35}O_3$) the *acid stearate* ($KO,HO,2C_{36}H_{35}O_3$). *Stearate of lime* ($CaO,C_{36}H_{35}O_3$). *Stearate of silver* ($AgO, C_{36}H_{35}O_3$). *Stearate of ethyl* (stearic ether) ($C_4H_5O,C_{36}H_{35}O_3$).

Stearanilide or *phenyl-stearamide* is obtained on distilling stearic acid with excess of aniline. It crystallises in needles and contains

$$\left(N,\left\{\begin{matrix}C_{36}H_{35}O_2\\C_{12}H_5\\H\end{matrix}\right.\right).$$

For the economical applications of stearic acid, see CANDLE MANUFACTURE; SOAP.

STEARIN. [STEARIC ACID.]
STEAROCHLORHYDRIN. [STEARIC ACID.]
STEARONE. [STEARIC ACID.]
STEAROPHANIC ACID. [STEAROPHANIN.]

STEAROPHANIN. ($C_{38}H_{36}O_4$). *Anamirtin.* A fatty matter described by Francis as existing in the *Anamirta Cocculus*. By saponification it yields *anamirtic* or *stearophanic acid*, which Hanitz considers to be identical with *stearic acid*.

STEAROPTEN. Volatile oils, as obtained by distillation from plants, appear, like expressed oils, to consist of two substances; one solid, which has received the name of *stearopten*, and the other liquid, called *elaopten*: the former generally crystallises when the oil has been long kept.

Camphor is the most remarkable substance of the class of stearoptens. It is obtained by distillation with water, and in the plant is mixed with camphor-oil, from the gradual oxidation of which it appears to be produced. [ESSENTIAL OILS.]

STEEL. [METALS, *Iron.*]

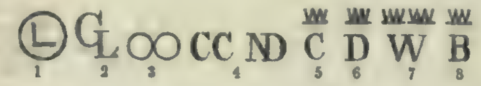
STEEL ENGRAVING. [ENGRAVING.]

STEEL MANUFACTURE. Iron possesses qualities which render it applicable to innumerable purposes in the arts; but there are some uses for which it is not sufficiently hard, and this defect is supplied by converting it into steel.

At Eisenärzt in Styria the manufacture of steel has been carried on ever since the 8th century, and yet the exact nature of the operation is perhaps even now imperfectly understood. It is generally admitted that steel is an intimate compound of iron and charcoal; for soft iron contains a considerable portion of charcoal, and it is by no means clear that the quantity is increased in the process of steel-making. Therefore we must conclude that some more intimate union is effected between them when iron is converted into steel. On this point we shall touch again after describing the manufacture.

Hitherto Swedish and Russian bar-iron have been almost exclusively employed in the manufacture of the best steel; the preference given to this iron is decided, though from what cause it arises has not been satisfactorily made out. We may, however, remark that the foreign iron used is made from magnetic iron-ore with charcoal; while British iron is obtained mostly from the impure carbonate of iron, called argillaceous iron-ore, or from hæmatite, which is a peroxide of iron, and both of these are reduced by employing coal, or coke prepared from it.

Bar-Steel is made, with few exceptions, from the Swedish and Russian iron, the bars of which are marked *hoop l* (1), *gl* (2), and *double bullet* (3); these are the best kinds. Iron of lower quality is also used, such as (4), which is a Russian iron, and *c and crown* (5), *d and crown* (6), which are Swedish irons. There is a medium quality, namely, *w and crowns* (7), *b and crown* (8); these also are Swedish.



These steel irons are imported almost exclusively by English merchants residing in Hull. The limited quantity of the fine iron allowed to be produced from the mines of Danemora in Sweden accounts in some degree for the high price at which they are sold.

Bar-Steel. The usual operation in large steel-works is first to cut the bar-iron into certain lengths. The closed vessels in which the bars are heated are usually twelve feet in length, and divided into two cells or troughs, on the bottom of which the workman strews charcoal to the thickness of about an inch. Upon this he places on their flat side a layer of bars; then about three-fourths of an inch more of charcoal is added; on this another layer of bars; and so on till the troughs are filled. These are then covered with a ferruginous earth coming from the grinding-stones, called wheelswarf, to the thickness of about eight inches. All the apertures of the furnace are closed with loose bricks and plastered over with fire-clay. The fire is then lighted, and in four days and nights the furnace is at its full heat; at which it is kept for several days, according to the degree of hardness required. In order to be able to test the progress of the carbonisation, a hole is left in one of the troughs near the centre; three or four bars are placed in the furnace in such a manner that the ends come through this opening, and after the sixth day one is pulled out. If the iron be then not sufficiently carbonised, the heating is continued from two to four days longer. A bar is drawn every two days; and when the iron is completely converted, the fire is heaped up with small-coal, and the furnace is left to burn out. It requires from this period fourteen days' time to cool sufficiently to allow a person to go in and discharge the steel. The cells or troughs must be kept completely air-tight; the smallest crack will open when the furnace is hot, and admit the air: this of course frustrates the object of the operation, and any steel which has thus suffered is placed aside to be reconverted. It is of the greatest importance to give the iron the exact quantity of carbon required and no more. For coach-springs, the iron must *not* be converted to the centre. For common cutlery, sheer steel, and for purposes where steel has to be welded to itself or to iron, the conversion should be low, and gradually disseminated throughout the whole thickness of the bar. For double sheer steel, the conversion should be somewhat harder than the preceding. For files, and all instruments where resistance or fine cutting edges are required, the conversion should be hard, and the iron fully carbonised throughout the bar.

No definite rules can be laid down to enable the uninitiated to judge of the temper or degree of hardness of a bar of steel; but by habit workmen soon acquire the means of distinguishing between the different degrees of hardness of two pieces of steel. This knowledge of the degree of temper is of great importance to the steel maker; for a file, made from soft steel which would be valuable for welding purposes, would be useless in the arts; while a coach-spring made from steel hard enough to make a file could not be applied to its intended purpose.

A converting furnace contains generally fifteen tons of iron; and there are some large enough to hold eighteen to twenty tons. The bar-steel, when discharged from the furnace, is partially covered with small raised portions of the metal; and from the resemblance of these to blisters, the steel is called *blistered steel.* It has been found by the experiment of placing a bar of Swedish and one of Staffordshire bar-iron in the same furnace, that the former was much blistered, while the latter had scarcely any blisters larger than a pea. At one time it was common for the steel-maker to receive orders for steel *well blistered.* This arose from a mistaken idea regarding the perfection of the steel; it being supposed that the more it was blistered, the more it was carbonised, and consequently that its quality was indicated thereby; now, however, manufacturers are better informed, and steel so blistered is complained of.

Bar-steel as it comes from the converting furnace is used for various purposes without refining; those parts which are free from flaws and blisters are broken out and hammered or rolled to the sizes required by the manufacturer for files, edge-tools, table knives and forks, coach-springs, and a great variety of common agricultural implements. It is also manufactured into what is called *single* and *double sheer steel*; for this purpose the converted bar is selected of an equable degree of hardness, and broken into pieces of about two feet in length; these are taken to the forge, heated to a full cherry red, and hammered into bars two inches by three-quarters of an inch in thickness; six of these pieces are put together and kept firmly so by a hoop, which is fixed at the end of a handle, thus—

They are then placed in a hollow fire urged by a soft blast, and heated gradually up to a full welding heat, during which the workman covers the surface with clay beaten very fine; this runs over the surface, and to some extent prevents oxidation. When fully heated, they are placed under the hammer, carefully welded together, and drawn into a bar of about two inches square at the same heat; the other end is then put into the fire and welded in the same way. This is termed *single* sheer steel. It is made *double* by nicking the bar in the middle and doubling it together, giving a second welding heat, and drawing it out as before to a bar of about two inches square; it is then *hammered, tilted,* or *rolled* to the size required; by this process *bar-steel* becomes more homogeneous, of a finer texture, and any instrument made of it will receive and retain a finer edge; the steel is also rendered much tougher, which condition is supposed to arise from the abstraction of a small portion of carbon, and the mechanical elongation of the fibre by these doublings, &c.

In Sheffield, where the steel manufacture is carried on to a larger extent than in any other town in the world, many manufacturing firms confine their operations exclusively to those above described: namely, making *bar* steel, in the two forms of *blister* and *sheer,* without including the making of *cast*-steel, or the fashioning of steel goods. The sheer-hammers, employed in the production of sheer steel, are very massive machines, having iron heads of twenty cwts. or more, faced with steel. The blows of these hammers, acting on heated bars of steel, greatly change their character; the blistered steel loses all its blisters and flaws, acquires a uniformity of character throughout, and becomes much more malleable and tenacious. According to the degree in which it is welded or sheered, so does the steel become applicable to a large number of practical purposes.

Cast Steel is the steel employed for the best goods. Cast-steel was first made by Mr. Huntsman, at Attercliff, near Sheffield, in 1770; since which time the manufacture of it has very much increased. It is steadily superseding the use of bar or sheer steel, on account of the equality of its temper, and the superior quality as well as beauty of the articles which are made of it. The process adopted is that of taking bar steel converted to a certain degree of hardness and breaking it into pieces of about a pound each; a crucible charged with these is placed in the melting-furnace, similar to that used by brass-founders. The furnaces are 20 inches long by 16 inches wide, and 3 feet deep. The most intense heat is kept up for two hours and a half or three hours, coke being used as fuel. When the furnace requires feeding, the workman takes the opportunity of lifting the lid of each crucible and judging how long the charge will be before it is completely melted. All the crucibles are usually ready about the same time. They are taken out of the furnace, and the liquid steel is poured into ingots of the shape and size required: the crucibles are immediately returned into the furnace; and when the contents of all have been poured into the moulds, the crucibles are again charged. They are used three times, and then rejected as useless. The ingots are taken to the forge-tilt or rolling-mill, and hammered into bars or rolled into sheets, as may be required. The celebrated *wootz,* or Indian steel, is cast-steel; but it is generally so imperfect as to resemble cast-iron rather than cast-steel. It is, however, made of iron obtained, as the Swedish is, from the magnetic ore. Wootz is made by the natives from malleable iron, packed in small bits with wood in crucibles, which are then covered with some green leaves and clay: about two dozen of these crucibles are packed in one furnace; they are covered with fuel, and a blast given for about two hours and a half, which terminates the operation. When the crucibles are cold, they are broken, and small cakes of steel are obtained in the form in which it comes to England.

This making of cast-steel is a remarkable operation. The heat of the furnaces is believed to be higher than any other known in English manufactures. The ingots weigh from about 40 to 200 lbs. each, according to the purposes to which they are to be applied. No less than four to five tons of coke are needed for smelting one ton of steel.

The *tilting* of steel is a process of hammering, mostly for cast-steel. The steel is heated to a certain temperature, and hammered all over for a considerable time; this closes the pores, and renders the metal as close and compact as possible. The steel for the best articles is both cast and tilted. *Case-hardening* is an operation whereby articles made of malleable iron or cast-iron are superficially converted into steel by heating them with charcoal in a crucible.

Relations of Steel to Iron.—The steel manufacture is just now in a transitionary state; several new processes of a highly curious nature have been introduced by Heath, Clay, Bessemer, Uchatius, and others, not fully successful, perhaps, but significant of the future. Most of these depend on a study of the relations between iron and steel, in a way which we shall briefly describe.

With respect to the composition of steel and the nature of the mixture necessary to constitute it, differences of opinion have long existed. The question even now is considered by some as hardly decided, whether carbon is indispensably necessary to its formation, and whether certain substances or metals, especially silicon, may not give rise to it; and it is generally admitted that phosphorus is always present. Berzelius mentions iron containing manganese as particularly eligible, and yet analyses show that this metal is not present in steel in most cases. An experiment performed by Mr. Pepys in 1815, seems not only to prove the necessity of carbon, but also that the diamond is capable of producing the same effect. In order to get rid of the objection that the carbonaceous matter of a common fire might supply carbon when iron and diamond were heated by means of it, he placed diamond-powder in a piece of pure soft iron wire; and having properly secured it, he heated it by means of voltaic electricity: after a few minutes' heating, the diamond had disappeared, and the interior surface of the iron was converted into perfect blistered steel, which, being heated to redness and plunged into cold water, became so hard as to resist the file and scratch glass. Some years since a method was discovered by Mackintosh of converting iron into steel by means of the carbon of carburetted hydrogen gas. Gay Lussac found that during fusion steel loses much silicon and a little carbon. Brande has found that when the carbon has fallen short of one per cent., the steel was deficient in hardness; and when it has exceeded this proportion, the dies have split or not stood their work. He states, at the same time, that minute quantities of other bodies appear to influence the quality of steel; and that unless it contain phosphorus it cannot be depended on for the manufacture of dies in coining. Dr. Thomson examined some cast-steel furnished him by Mr. Buttray, a steel-maker near Glasgow. The general result of his trials gave him a composition which approaches 20 atoms of iron + 1 atom of carbon; and this he thinks likely to be the constitution of cast-steel, an opinion corroborated by the fact above stated by Mr. Brande. Mr. Faraday and Mr. Stodart published in the 'Phil. Trans.' for 1822 a valuable series of experiments on alloys of steel, from which it appears that by combining steel with other metals its quality is improved. A very minute addition was found sufficient to produce a good effect: thus one 500th of silver gave an alloy harder than cast-steel; one 100th of nickel gave a very hard alloy, susceptible of a fine polish; alloys of rhodium and platinum were also formed; and these, with the alloys of iridium, osmium, and palladium, formed the most valuable compounds.

Mr. Binks, in a paper read before the Society of Arts in 1857, on the nature and properties of steel, described the experiments which had led him to the following conclusions: That the substances whose application to pure iron convert it into steel, all contain carbon and nitrogen; or that nitrogen has access to the air during the process. That carbon alone added or applied to pure iron, does not produce steel; and that neither does nitrogen alone produce it. That it is essential for both carbon and nitrogen to be present. That both exist substantially in steel after its conversion. That such presence is the real cause of the distinctive physical properties of steel from those of iron. That presumptively, though not demonstratively, the form of combination is that of a triple alloy of iron, carbon, and nitrogen.

It has for many years been believed in England, that Swedish iron derives some of its valuable steel-making properties from the presence of a small quantity of manganese; hence the question—might not manganese be profitably added to English iron? Mr. Heath took up the subject, spent a fortune upon it, greatly enriched Sheffield, and died broken-hearted. In 1839 he devised a mode of combining carbon with manganese, to produce a carburet, which converted English iron into very good steel. The manganese appeared to him to act as a sort of detergent, taking away certain impurities from the iron. Unfortunately for his interests, he *improved* the process; he put into the furnace the elements of the carburet (carbon and manganese) instead of the carburet itself, thereby lessening the expense. He neglected to obtain a second patent for this improvement; the Sheffield manufacturers saw the flaw, made the new steel without paying him any royalty and defied him. The suit of Heath *v.* Unwin, carried on for eleven years, in all the various forms known to English law and equity, ruined Mr. Heath, who died in 1850. His widow succeeded in obtaining a small interest arising out of the patent, but quite disproportionate to the importance of the invention. Mr. Webster has stated that, between 1839 and 1855, buyers of Sheffield cast-steel goods benefited to the extent of *two millions sterling* by the lowering of prices due to Mr. Heath's process.

Steel is of a lighter gray than iron. It is susceptible of receiving a very high polish, and this is greater as the grain is finer. When steel is hardened its volume is increased. When heated to redness, and slowly cooled, it is scarcely harder than iron; but by very rapid cooling it becomes hard, and so brittle as to be readily broken. The fracture is usually fine grained. In ductility and malleability it is much inferior to iron, but exceeds it greatly in elasticity and sonorousness. It may be subjected to a full red heat, or 2786° Fahr., without melting, and is therefore less fusible than cast-iron, but much more so than wrought-iron. Pieces of steel which have not been cast may be readily welded together or with iron; but after casting, the operation is more difficult. In order to give to steel the different degrees of hardness required for various purposes to which it is applied, it is subjected to the process of *tempering*. The higher the temperature to which it is raised, and the more sudden the cooling, the greater is the hardness. Thus when immersed in mercury the hardness is greatest, on account of the good conducting power of the metal, and its consequent ready abstraction of heat. After this comes acidulated water, salt water, common water, and lastly oily or fatty bodies. It is found that, according to the degree to which steel is tempered, it assumes various colours, and formerly these colours served as guides to the workman; now, however, a thermometer, with a bath of mercury or of oil, is employed, and the operation is performed with a much greater degree of certainty. Into this bath the articles to be tempered are put, with the bulb of the thermometer graduated up to the boiling-point of mercury. The tempering heat varies from 430° Fahr. (for lancets) to 600° (for pit saws).

Puddled and Bessemer Steel.—Arising out of the inquiries concerning the relations between iron and steel, several new modes of making steel have recently been introduced or proposed. Hitherto, most English steel has been made by the *converting* process, already described; but on the Continent it is more usual to adopt what is called the *raw* method, puddling the metal in a charcoal furnace. The English method *raises* the amount of carbon in or with *bar*-iron up to about 1 per cent.; the Continental method *lowers* the amount of carbon in or with *pig*-iron from 4 to 1 per cent. Riepe's method, patented in 1850, and worked some time by the Low Moor Iron Company and the Mersey Steel Company, is for making a kind of steely iron by the puddling process, good enough for most common purposes—hard and unyielding, or soft and silky, according to the extent to which the process is carried. To produce this steel, pig-iron is thrown into a puddling-furnace [FURNACE; IRON MANUFACTURE], together with a little iron slag, salt, clay, and oxide of manganese; the molten metal is worked or puddled beneath the scum, and is worked up into balls or blooms at a certain stage. Captain Uchatius, engineer of the Imperial Arsenal at Vienna, has devised a method of making steel in which (as he thinks) English iron would suit as well as Swedish or Russian. He brings the iron to a granular state, by running it from a furnace into agitated cold water. These grains are mixed with some cheap oxygen-yielding material, such as spathose iron-ore, put into a crucible, and melted in a cast-steel furnace. The pig-iron gives up some of its carbon and its earthy impurities to the oxygen, and becomes steel. The smaller the granules, the softer the steel. Uchatius produces 25 lbs. of steel from 24 lbs. of granulated iron, 4 lbs. of spathose ore, 4 lbs. of oxide of manganese, and a little clay. Sir F. Knowles has introduced a method in which a retort instead of a crucible is used; while the crude iron is mixed with hot gases rich in carbon. The processes of Uchatius and Knowles seem better adapted for the laboratory than for large manufacturing operations. Other modes of producing steel directly from the crude iron have been introduced, with varying success, by Clay, Saunderson, Plant, Nasmyth, Mortier, and others.

But of all the novelties connected with the steel manufacture, those by Mr. Bessemer have attracted the most notice within the last few years. He has taken out five or six patents on the subject. In his hands the difference between iron and steel is simply one of degree, for it is not easy to say where Bessemer iron ends and Bessemer steel begins. It was at the Cheltenham meeting of the British Association, in 1856, that the process first attracted attention. Mr. Bessemer conceived that pig-iron might be converted into malleable iron, and then into steel, without any additional consumption of fuel. Pig-iron contains more carbon than the others; and if oxygen could be made to burn a portion of this away, the object would be accomplished. How, then, to expose molten pig-iron to the action of oxygen? He decided that a *blast* would best effect this. He formed a fire-brick furnace of small size, with *tuyère* holes near the bottom, and two larger holes half-way up. Molten pig-iron flowed at once from a blast-furnace to this small furnace or cylinder, and a blast was driven into the cylinder. A violent commotion ensued, and an intense heat resulted from the combination of the oxygen in the blast with the carbon in the molten mass. Volumes of flame and a few sparks were produced, and then a sort of eruption of slag. Flames again appeared; for some of the oxygen formed an oxide with some of the iron, and acted as a kind of solvent for sulphur and earthy matters. The pig-iron lost about 12 per cent. of its weight during this process. The rich slag thrown out might be afterwards treated with carbon gases, and made to yield more iron. When the flames and sparks had subsided, a plugged hole was opened, and the metal poured into an ingot-mould, without leaving any cinder or oxide. The process took little more than half an hour, and no fuel was used. While in the cylinder, the metal was not a mere pasty mass, it was a boiling fiery fluid. At a certain stage, the iron became crude steel. By continuing the boil, more carbon was driven out, and purer steel resulted. In short, any medium between the softest iron and the hardest steel might be produced by varying the duration of the process. One kind, called by Mr. Bessemer *semi-steel*, is more elastic, harder, and stronger than bar-iron, but not so hard and fine as steel; it is useful for light and strong purposes; it is more difficult to roll than iron, but is stronger and more durable, and is therefore considered to be cheaper in the end.

In the three years next following this announcement of Mr. Bessemer's invention, the comments took the whole range between the highest praise and the most marked disapproval. The inventor and his friends claimed for the novelty a diminution of labour, time, and cost; the production of a metal more homogeneous than by the common method; no residue of wasteful slag; and the power of producing ingots of any weight from one to seven or more cwts. The Llanelly Tin-Plate Works supplied Mr. Bessemer with some pig-iron such as they used for producing the best sheet-iron: he converted it into a soft ingot, which was wrought at a white heat into a slab by the force of a steam-hammer, and then rolled into very good sheet-iron for tin-plate. Mr. Adams stated that an amateur might easily make a bit of steel, by melting 4 ozs. of cast-iron in a crucible, pouring it into the bowl of a large tobacco-pipe, and using the stem as a blow-pipe. On the other hand, most of the manufacturers found fault with the Bessemer process. Some of them said that, although the process removes the carbon and silicon more completely than the ordinary method, and the sulphur about as well, it leaves the phosphorus untouched, which they regarded as a fatal blot. Others made trial of the process, and declared the iron or steel produced to be bad. In 1859, after patenting several modifications of his plan, Mr. Bessemer described his process, in a somewhat altered form, before the Institute of Civil Engineers. He had been endeavouring to get rid more completely of the sulphur and phosphorus. He used Swedish iron instead of English for the best steel, poured the molten metal into cold water instead of into a large mould, re-melted it, and finally poured it into small moulds. Other changes had been made in the apparatus and the process. Some of the ingots exhibited possessed wonderful tensile power. A bar 3 inches square was bent round until the outer curve was lengthened from 12 to 16¾ inches, and the inner lessened from 12 to 7½ inches, cold, and without a flaw. Four iron rods, 1¼ inches diameter, were twisted cold into a cable; the rods stretched one foot in four during the process, and thinned out in inverse proportion. A steel bar, 2 inches square, was twisted cold into a spiral at an angle of 45°. A round steel bar was hammered cold into the form of a horse-shoe.

At the present time, the Bessemer process is under probation. Works have been erected at Sheffield to put it in operation; and similar establishments have been founded in several Continental states. By this means the system will obtain that which alone can determine its value—a fair trial on a large scale. Persons of moderate views believe that the semi-steel will become useful for railway purposes, as being harder than bar-iron, and for marine engine-work, because it is lighter than iron for equal strength. How far fine steel can be profitably produced, without the converting process, is still a disputed point.

In 1853, Sheffield had 160 steel-converting furnaces, and 1495 cast-steel "holes"—about 16 holes to a casting-furnace. Of the 20,000 to 40,000 tons of Swedish iron annually imported, nearly all goes to Sheffield to be converted into steel. Including Russian and English iron, it is supposed that about 50,000 tons are annually made into steel, of which 30,000 tons are cast-steel. The value of this quantity is roundly estimated at about 1,500,000*l.* yearly.

STEELYARD. [WEIGHING MACHINE.]

STEELYARD, MERCHANTS OF THE, a body of aliens who enjoyed various commercial privileges in England from an early period to the middle of the 16th century. "The emperor's men," mentioned in some ordinances of Ethelred II. (A.D. 978-1016) as trading to England, were the predecessors of the merchants of the Teutonic Guild. In 1220 the merchants of Cologne had a hall or factory in London, for the legal possession of which they made an acknowledgment to the king. "It seems that this Gildhall, by the association of the merchants of other cities with those of Cologne, became in time the general factory and residence of all the German merchants in London, and was the same that was afterwards known by the name of the German Gildhall ("*Gildhalla Teutonicorum*"). (Macpherson, 'Annals of Commerce,' i. 383.) In 1235, Henry III. gave them permission to attend fairs in any part of England, and also to buy and sell in London, saving the liberties of the city; and they were exempted from several customs and payments. In the 15th century we find the Hanse merchants engrossing the privileges of the above ancient incorporation, Cologne being a member of the League, and the whole of the German merchants resident in London probably belonging to one or other of the Hanse towns. At least, after 1475, they had but one factory in London, which was the Steel-yard, or Steel-house, as it was sometimes called, situate a little east of Dowgate, between Thames Street and the river. The Thames-street front was fortified with three portcullised gateways; and the whole was inclosed by strong walls, within which, more than once, and especially on the irruption of Wat Tyler's mob in 1381, the Hanse merchants saved themselves, while the Flemings and other foreigners fell victims to the national prejudice. In the interior was the great hall, adorned with pictures by Hans Holbein, in which the corporation held their councils and partook of their feasts. On the west side of the hall was a garden, adorned with vines and rare fruit trees. The Thames front was a quay, with all the conveniences then known for embarking or disembarking goods. The remainder of the area was occupied by lofty warehouses and streets of booths for the reception and display of the necessaries and luxuries imported from the north, south, and east,—fine cloths, wines, silks, dried fruits, spices, with hemp, tallow, furs, salt-fish, and iron. Strict order was preserved in the building, whose gates were shut at nine in the evening; and to the corporation was entrusted the care and repair of Billingsgate; every master being under an obligation to provide harness for war, the same as a native. The old building was destroyed in the fire of London in 1666. That which succeeded differed little from the other erections in its neighbourhood. The Steelyard was in the parish of Allhallows, at which church the members attended, and which they embellished with painted windows. After the fire of London, on the rebuilding of the church, they contributed the carved oak screen which still separates the choir from the nave. In 1673, the inconvenience of attending a service in a foreign language induced them to petition for one of the abandoned churches, and that in Little Trinity Lane was granted to them, which has thenceforward been used by the German residents in London for divine service in their own tongue. In 1475, Edw. IV. entered into a treaty with the Hanseatic League, by which the privileges of the London factory were placed on a more secure foundation, instead of being granted only for a short period, and being at times curtailed, and even occasionally suspended. By way of settling former disputes, it was thought worth while to pay them 10,000*l.*, or rather to remit customs duties on their goods to that amount. The king was to appoint two or more judges to act without the ordinary legal formalities in all civil and criminal cases between the Hanse merchants and English; and similar regulations were to be adopted in reference to English subjects residing at the Hanse towns. The fee simple of the Steelyard was conveyed by this treaty; also the Steelyard at Boston, and a house at Lynn. Under this treaty and their old charters, the Hanse merchants of the Steelyard were enabled to monopolise certain branches of trade, in which they were exempted from duties payable by other traders; and by their combination and capital, they were doubtless formidable competitors in other branches of foreign trade; but though the activity of foreigners might be tolerated while native capital was wanting, yet a trade from which English merchants were virtually excluded could not possibly be permanent. The industry and energy of the English trader made him a formidable competitor. He not only, in spite of the troubles of the wars of the Roses, exerted himself to supply domestic wants, but he actually, as is noticed above, had pushed himself into the traffic of the Baltic. In addition, the requirements of commerce had introduced the use of larger vessels; which could not well be adopted by the Hanse merchants, as they could not come above London Bridge. All things were working against the interests of the Steelyard.

In 1505 a rival interest was created, by a charter granted to the Company of Merchant Adventurers for trading in woollen cloth to the Netherlands. The merchants of the Steelyard were bound in heavy penalties not to interfere with the trade of this new incorporation, which soon became a powerful rival, not only to the German merchants, but to the merchants of the staple. In 1551, various allegations of the Merchant Adventurers, with the counter-statements of the merchants of the Steelyard, were put into the hands of the solicitor-general and the recorder of London, upon whose report the council came to a resolution that the Steelyard merchants had forfeited their privileges, their charters being contrary to the laws of the realm. The council reported that no particular persons or towns being mentioned in these charters, the corporation had extended their privileges to whomsoever they pleased; that English subjects had not enjoyed reciprocity of privileges in the Hanseatic towns; that their English trade was no longer confined to the Hanse towns; that they had engrossed almost the entire trade carried on by foreigners in the kingdom; lastly, that they had reduced the price of wool, and also of corn by their importations of foreign grain. The articles which they imported, besides grain, are stated to have been cordage and other naval stores, flax and hemp, linen, cloth, and steel. The English Merchant Adventurers flourished on the ruin of the older incorporation, which however continued to linger until 1597, when the Emperor Rudolph having ordered the factories of the English Merchant Adventurers in Germany to be shut up, Queen Elizabeth directed the Lord Mayor of London to close the house occupied by the merchants of the Steelyard. The buildings and site of the Steelyard, however, remained in possession of the towns of Hamburg, Bremen, and Lübeck, as representatives of the old Hanse corporation, till 1853, when, having no use for them, they sold the property, for which it is said they obtained 72,000*l.*

(Strype's *Eccles. Mem.*, iii. 77; Anderson's *Commerce;* Macpherson's *Commerce;* Dr. Reinhold Pauli's *Bilder aus alt England*, which contains an essay on the Steelyard.)

STEERING APPARATUS. Various contrivances have been made of late years, some of great ingenuity, to remedy the inconveniences of the steering-wheel so long in use. Larger vessels requiring more powerful apparatus for moving the rudder, many patented inventions have appeared which have introduced the use of cogs and screws; but no one has yet succeeded in effecting such results as would warrant its general adoption. One, however, that by which the steering-wheel is situated in the fore part of the vessel, its motion being communicated to the rudder by ropes, chains, or rods, was used by Symington in his tug-boat upon the Forth and Clyde Canal, about 1802; but whether its subsequent adoption in North America is in any degree to be attributed to that circumstance, we are not aware. The peculiar arrangement of the river steamers of America, which have the engines and some of the cabins on deck, combined with their great length, renders it impossible for the steersman, if in the situation usual in the steam-vessels of this country, to see his course; and, therefore, he is usually elevated on a platform near the bow.

STELE, the name of any upright column, or tablet, on which were engraved decrees, funereal and other inscriptions, sometimes decorated with subjects in relief. The Egyptian steles, called *hutu*, placed in the tombs, have, during the 6th and 12th dynasties, scenes of family worship; but under the 18th and subsequent dynasties adorations to deities are represented: at all periods they have hieroglyphical inscriptions, dedications to sepulchral deities entreating certain benefits for the deceased, and other religious formulæ, or even family registers. Some are dated in the reign of the king under whom the deceased died. Other steles, dedications of temples, or invocations to deities on behalf of different monarchs, were placed in the adyta of temples. Granite, basalt, and calcareous stone were chiefly used. The Assyrian steles have generally a bas-relief of the monarch by whom erected, and a long account of his conquests, in cuneiform characters. The Greek sepulchral steles are often ornamented with figures of various deities to whom they were dedicated, scenes of family repasts, or last adieus, representations of the deceased, or floral and architectural ornaments, and inscriptions commemorative of the deceased. Public acts, treaties, and religious dedications, were often registered on steles. They are generally made of white, although occasionally of coloured, marbles. Some Carthaginian steles have dedications to Baal Hammon and Tanath, and representations of this goddess. (Layard's *Nineveh;* Stackelberg, *Die Gräber der Hellenen;* Hincks, *On the Egyptian Stele.*)

STELLIONATE, a word derived from *stellio*, the name of an animal of the lizard kind, mentioned by Pliny ('Hist. Nat.', l. 3, c. 10), and by Virgil ('4 Geor.', 243), is a term used in the Roman law to denote all such crimes, in which fraud is an ingredient, as have no special names to distinguish them, and are not defined by any written law. In general, wherever a civil action might be brought on the ground of fraud, there might be a criminal prosecution for stellionate. The term however is chiefly applied to cases where a person sells, exchanges, or transfers to one, property with respect to which he has already entered into a contract with another. It is also applied to cases of pledging another man's property, substituting base for precious metals, dealing in counterfeit or adulterated goods, and generally to the practice of any species of imposture. The punishment of stellionate was of necessity discretionary. Where the criminal was a person of distinction, the ordinary punishment appears to have been temporary banishment and degradation from his rank; and where he belonged to the lower orders, it seems to have been competent to inflict any punishment short of condemnation to work in the mines. ('Dig.', 47, tit. 20; Hellfeld, 'Jurispr. For.', s. 2067.) The term stellionate is used in the law of Scotland in nearly the same sense as in the Roman law. (Ersk., 'Inst.', 4, tit. 4, s. 79.)

STENCILLING is a mode of transferring a coloured pattern or design to the surface of cloth, paper, or other material. The pattern is cut through a stencil plate, usually a piece of sheet metal; and liquid or pasty colour is brushed over the plate, in such a way as to pass through the perforations, but not to reach those parts of the paper or cloth on which the uncut portions of the plate rest. Examples of the process will be found noticed under CARD-MAKING and PAPER-HANGINGS.

STENOGRAPHY, or the art of short-writing, is a term compounded of two Greek words, *στενός*, contracted, and *γράφειν*, to write. The invention of stenography among the Greeks is generally assigned to Xenophon the historian; but it is said that the art was first practised by Pythagoras, and that the poet Ennius was the first who adopted a system of short writing by which a person was enabled to follow a speaker. It is said, though upon no very certain testimony, that he commenced by employing eleven hundred marks of his own invention, and increased the number as circumstances required.

There are also writers who ascribe the invention of the art to Cicero; and it was certainly practised by him on account both of its brevity and secresy. He reminds ('Ad. Att.,' xiii. 32) his friend Atticus that he wrote (*διὰ σημείων*) by signs. The art was communicated by Cicero to Tiro, his freedman, who made considerable improvements in it, and is said to have been likewise the first person who applied it to the purpose of taking down public speeches. Eusebius attributes the invention to Tiro. The oration of Cato relative to the Catilinarian conspiracy was preserved by means of shorthand. The art was subsequently improved, and stenography became a fashionable accomplishment with the Romans. There is extant a work on the shorthand (*notæ* of the Romans) attributed to Tiro and Seneca, and printed in Gruter's 'Collection of Inscriptions.' Most of the writers of that age allude to the stenographic art in their works. Horace points out its brevity; and Ovid mentions its advantages in point of secresy. It is also commended by Ausonius, Martial, Manilius, and others. [NOTARY.] The Roman shorthand was very different from our own: the abbreviations, in general, appear to have resembled those adopted in ordinary writing, and which frequently occur in ancient manuscripts, as well as in early editions of Latin works. A very large collection of manuscript abbreviations is printed at the end of Göschen's edition of Gaius; and specimens of ancient Roman stenography are given in Lewis's 'Historical Account of Shorthand.' Some passages in the Roman writers, which have been supposed to refer to shorthand, appear to refer to writing in cipher.

The first English treatise on Stenography was published in 1588, by Dr. Timothy Bright, and dedicated to Queen Elizabeth. It was entitled 'Characterie, or the Art of Short, Swift, and Secret Writing;' and consisted exclusively of arbitrary characters, each of which represented a word. Two years afterwards appeared 'The Writing Schoolmaster,' in three parts, by Peter Bale. The system of Bale, like that of his predecessor Bright, was formed of arbitrary characters, instead of a combination of elementary marks or signs. Both systems were exceedingly crude, and difficult of attainment; requiring, as they did, for their practical application, a remarkable tenacity of memory; but they displayed great ingenuity as first attempts. The earliest effort to form a regular shorthand alphabet appears to have been made by John Willis, who in 1602 published 'The Art of Stenographie, or Short Writing, by Spelling Characterie.' The work went through numerous editions. The alphabet was formed of the most difficult and complex characters, which were ill adapted for joining, their formation consuming treble the time required for forming the characters in any of the modern systems of moderate celebrity. Willis was followed by a host of imitators, none of whom, however, effected any material improvement. In 1618 appeared a treatise upon Stenography by Edmond Willis, which was followed in 1630 by that of Witt; in 1633 by that of Dix; and by a great number of others at short intervals. That of Rich, published in 1654, was praised by Locke. In 1753 was published the system of Mr. Thomas Gurney, which has since been so very extensively practised by various members of his family and others, in the houses of parliament, the courts of law, &c.

Among the more recent systems, that of Dr. Byrom deservedly occupies a very prominent position. He succeeded in forming an alphabet at once simple, precise, and practicable, as well as in rendering the general details of his theory exceedingly clear and intelligible. His system was incomparably superior to any which had preceded it. Although the treatise was completed by the year 1720, it was not published till 1767, after the death of the author, who, as he depended for support principally upon private tuition, obtained an act of parliament for the security of his invention. The doctor, in 1749, printed fifty copies of his work for the use of his particular friends. Since its publication it has been edited by several persons. Mr. Thomas Molineux, of Macclesfield, published an edition which he entitled 'An Introduction to Mr. Byrom's Universal English Shorthand,' which was popular for many years; and some years later, Mr. William Gawtress, of Leeds, published a 'Practical Introduction to Shorthand' upon the general principles of Byrom, which is one of the cheapest and most useful manuals of shorthand which ever appeared.

The system next deserving of notice is that of Taylor, which made its appearance in 1786, and is entitled 'An Essay intended to establish a standard for a universal System of Stenography or Shorthand Writing.' This author's system is superior to that of Byrom in several particulars; but principally in a greater brevity and simplicity of the alphabet, and the facility with which the various characters may be joined to each other; all points of the utmost value and importance. Some useful practical improvements upon Taylor's system have been made in Mr. Harding's treatise on the art. Dr. Mavor's system, though it obtained considerable popularity, is inferior to that of Taylor, on account of his alphabet requiring a greater number of strokes of the pen, and the characters being more difficult of junction. Since the publication of Dr. Mavor's treatise, many others of various degrees of excellence have been published, but it is needless to enumerate them; those who desire further information as to the history of the art will find much valuable matter in Mr. Lewis's 'Historical Account of Shorthand.' The alphabets on the next page will in some measure illustrate a portion of the foregoing remarks as to the improvements which have from time to time taken place.

To shorthand writers we owe full reports of the proceedings of parliament, of public meetings, and of the courts of law. The newspaper press has indeed given a powerful stimulus to the cultivation of the art, by affording a respectable livelihood to a numerous body of individuals. In addition to what it has done for the daily and weekly press in particular, shorthand is used for taking down sermons, scientific lectures, &c. By students of divinity, medicine, law, or others, who may wish to preserve the whole or parts of discourses or lectures on scientific or other subjects, shorthand may be studied with great advantage. The art, however, is not to be acquired without the diligent application of many months, and it also requires considerable manual dexterity, though worthless treatises and travelling teachers of stenography occasionally assert the contrary.

We shall now give a brief summary of the principles of stenography, according to the system of Taylor, as improved by Harding.

Of the Alphabet.—The vowels are represented by points, a period standing for *a*, *e*, and *i*, and a comma for *o* and *u*. The single consonants of the shorthand alphabet amount only to sixteen, *c* and *z* being rejected as unnecessary, the former having both a hard and a soft sound, similar to *k* and *s*, as in the words "command" and "sentence;" *s* is therefore always substituted for *c*, where the letter has a soft sound, and *k* where it has a hard sound: *f* and *v*, being similar in sound, are both represented by the same character. For the same reason, *g* and *j* are represented by one character, as are also *k* and *q*. Characters are also assigned to double consonants, such as *ch*, *sh*, and *th*. These double consonants conduce to both perspicuity and expedition. The vowels are distinguished from each other by their position. For instance, should the period be placed over the top of a consonant, it signifies *a;* if placed against the side, or opposite the centre of the consonant, it becomes *e;* if placed at the bottom *i*. The personal pronoun *I* is represented by a mark similar to the top part of a note of admiration. The comma is *o* when placed in the same situation as the dot or period for *a*, and *u* when in the same situation as the dot for *e*. Where vowels have been generally omitted, either through the haste of transcribing remarks on any subject, or for expedition in following a speaker, they ought, where such a course is rendered necessary, to be supplied immediately afterwards, while the subject written is fresh in the recollection of the writer. In all words which have neither incipient, terminative, nor long vowels, no middle vowel should be expressed unless some peculiarity may render it expedient or necessary to deviate from this general rule. A word of more than one syllable, having a long vowel in it, must generally have that vowel expressed, because the long vowel being found in that syllable which is most distinctly heard in pronunciation, affords the greatest help in reading; at the same time, however, when a word of more than one syllable consists of several consonants, even the long vowel may be frequently omitted. The various characters of the alphabet represent, when placed by themselves, a number of small words. For example, the *a* or *an* is written by dot; *the* and also *and* by a comma, the former being written above the line, and the latter below. The consonant b represents the word *be, by, been;* d, *do, did, done;* f, *off, of; if;* g, *God, give, go, good;* h, *have, he;* k, *know, known;* l, *Lord, all, will*, and so on throughout the alphabet. For the attainment of practical proficiency in the art, it is necessary that the alphabet should be acquired so perfectly as to be written correctly four times in a minute. It is necessary also in this place to explain that *d* and *r*, which in the alphabet appear to be precisely the same in form, are distinguished by the former, when joined to another consonant, being written downwards, and the latter upwards.

Of Prepositions and Terminations.—Prepositions and terminations are the letters or signs by which the first and last syllables of words are represented. The whole of the single and double consonants of the alphabet are employed in denoting the beginnings or endings of words; in which situations the letters are not joined to the other part of the word, but placed so close as to show their connection and prevent their being mistaken for separate and independent words. The letter *b* represents the prepositions *abs, obs, &c.;* and the terminations *ble, ible, bly;* the letter *d*, the prepositions *de* and *des*, and the terminations *dom, end, ened*, &c.; the letter *f*, the preposition *for* and the termination *ful;* and the other alphabetical characters are appropriated in a similar manner. Besides the consonants several arbitrary marks are also used to denote the endings of words. In many cases a preposition and a termination together are all that are necessary to represent a word.

Of Arbitraries.—In the system of Taylor very few arbitraries are employed. They do not exceed twenty in number and may generally be employed with advantage, which is more than can be said of the arbitraries of several other systems. The experienced shorthand writer may readily, and with much benefit to himself, increase the number of these marks as occasion may require. For instance, the individual who acquires the art of writing shorthand for the purpose of its practical application in a court of law, may readily assign arbitrary marks for such technical terms or lengthy words as are of most frequent recurrence. In the same manner the student of medicine or divinity may also form such characters to suit his own peculiar pursuit; and those persons who practise shorthand for a variety of purposes may in like manner adapt them to the several subjects on which they may have occasion to take notes. The great capabilities of arbitrary characters in these respects have not, we believe, been pointed out as they might have been, either by Mr. Harding or any other author into whose system we have looked.

Of the mode of Spelling.—The great aim of shorthand being to represent words by the fewest simple characters possible, all letters which are not distinctly sounded in any word must be omitted, except in cases where their retention may seem necessary. If words are written as they are pronounced, every silent letter will of course be omitted. In following a speaker, however, it is necessary that all vowels should be omitted, or otherwise it will be impossible to take more than the substance of his remarks. Where, however, proper names occur, they should either have the vowels inserted or be written in longhand: the latter method is most advantageous, as the names, when so written, serve as rallying-points to the eye in deciphering shorthand notes. Where the vowels are omitted in general writing, the rule is to write such of the consonants as are sounded in the pronunciation of any word.

Of Miscellaneous Modes of Abbreviation.—As in following a speaker all the vowels require to be omitted, and the consonants only written, so all the small words in a sentence are likewise left out. In some cases, however, where the speaker is deliberate and the writer is expert, nearly all the words may be expressed. In the abridgement of sentences of course the writer is guided by his own judgment and the necessities of the case. The different tenses and moods of the verbs are generally expressed in the English language by the help of other verbs, as *shall, have, had, can, could, may, must, be*, &c. These being written by their first consonant, may be joined together; but a point should be inserted over the characters, to signify that they are the first letters of words in the sentence. The radical part of a word too may often be sufficient to denote the whole word, as *exp.* for expenses, *pos.* for possible, and so forth. A mode of contraction much used in common writing is to express the first and last consonants of a word, inserting a dash in the middle to show that it is deficient. This plan may be adopted in shorthand writing, or the common letters may be occasionally used. If the characters cannot be distinguished by the plan first pointed out, the termination may be written under the first consonant. The usual abbreviations in longhand can be adopted in shorthand. If a part of a sentence is to be repeated, a line may be drawn under it, and a caret placed where the repetition should be read.

As our object is not to supply a manual by which the art of shorthand may be acquired, but rather to afford some information concerning its leading principles, we have omitted explanations of minor importance.

STEPPES. [Plains.]

STEREOGRAPHIC. This word, which is derived from *στερεός*, "solid," and *γράφειν*, "to draw," and which therefore ought to be applied to every method of representing a solid in a plane, has nevertheless a limited technical sense, being applied to that projection of a sphere in which the eye is at a point in the sphere, and the plane of projection is the great circle of which the eye is at the pole, or a plane parallel to it. This mode of projection was known to Hipparchus, and was first described in the work on the planisphere attributed to Ptolemy.

The stereographic projection has two remarkable properties. The first is, that all circles are projected either into straight lines or circles. Those which pass through the eye are of course projected into straight lines; in every other case the projection is the Subcontrary section of a cone, which has its vertex at the eye, and the circle to be projected for its base; consequently the projection is a circle. As much of the circle as lies below the plane of projection (the eye being considered as above it) is projected inside the great circle on which projection is made; and all the rest outside: when this projection is employed in maps, it is usual to place all the part of the globe to be projected below the plane of projection.

---

* As improved by Harding in the positions of the vowels.

The second property is, that the angle made by two circles which meet on the globe, is equal to the angle made, at the point of meeting, by the two circles which are the projections of those circles, the angle made by two intersecting circles being always that made by their tangents. This property is easily proved as follows: Draw through the point of intersection of the two circles (A and B) which are to be projected, two other circles (A′ and B′), which have the same tangents, and pass through the eye. Then the tangents of A′ and B′ at the eye make the same angle as those at the other point of intersection, that is, as the tangents of A and B at the point to be projected. But these tangents of A′ and B′ at the eye are parallel to the *projections* of the tangents of A and B at the point to be projected: whence the projections of these tangents of A and B make the same angle as the tangents themselves.

The first property was known to Hipparchus and Ptolemy: the history of the second is rather curious. The first writer who seems to have looked attentively for a discoverer was Delambre ('Mém. Inst.', vol. v., p. 393), who could not find it in Clavius, Stoffler, nor in any of the writers of the middle ages, who have treated pretty voluminously on the astrolabe, which word, as used by them, merely meant a stereographic projection. That it was mentioned (without demonstration) in the French Mathematical Dictionary of Savérien (1753), in an article which was copied word for word into the 'Encyclopédie,' was all that Delambre could then say of its origin. He afterwards, in writing his 'History of Astronomy in the Middle Ages,' found the proposition demonstrated in the 'Compleat System of Astronomy,' by Charles Leadbetter, London, 1728; but, judging from the rest of the work, he presumes that Leadbetter could not have been the discoverer. No claim was, however, at the time put in for any one else, and Savérien's article, which appeared in the 'Encyclopédie,' first called general attention to the property, and this can be traced to Leadbetter's work nearly. For we find that Savérien translated his article, word for word, from the second edition (1743) of Stone's 'Mathematical Dictionary.' Stone was a contemporary of Leadbetter, and several times refers to his writings.

On consulting the third edition of Dr. Harris's 'Lexicon Technicum' (1716), and feeling sure, with regard to that work, that such a proposition as the one called Leadbetter's would be stated, if it were then known, we turned to the article 'Spherick Geometry,' and there we found it, with a demonstration, enunciated as follows:—"All Angles made by Circles on the Superficies of the Sphere are equal to those made by their Representatives on the Plane of the Projection." The claim of Leadbetter is therefore overthrown. In the preface, Harris says that under (among others) 'Spherical Geometry' will be found entire treatises, which, if he mistakes not, are as short and plain as any extant. If this proposition had been new, he would probably have noted it here, particularly if it had been his own. We find however, finally, that the property has been shown ('Encyc. Brit.', 'Projection') to have been demonstrated by Halley in No. 219 of the 'Philosophical Transactions,' and is attributed by him to De Moivre or Hook.

The consequence of this theorem is, that any small portion of the sphere is projected into a figure very nearly similar to itself, so that any not very large portion of the earth preserves its figure with tolerable accuracy in the map. Hence some writers have said that there is no distortion in the stereographic projection, which is not absolutely true, though nearly so of countries which bear no greater proportion to the whole earth than most of them.

The mode of laying down the stereographic projection is briefly stated, and a diagram given, in the article MAP; it will be found at greater length in the memoir of Delambre above cited, or in any good work on the construction of maps.

STEREOSCOPE, from *στερεός* (solid), and *σκοπός* (a view, or *σκοπέω*, to view), an instrument by which two pictures of any object, taken from different points of view, are seen as a single picture of that object, having the natural appearance of relief or solidity.

The theory of the stereoscope is sufficiently discussed under SIGHT. The reflecting stereoscope was first described in a paper by Professor Wheatstone, entitled 'Contributions to the Physiology of Vision: Part I. On some Remarkable and hitherto Unobserved Phenomena of Binocular Vision,' read before the Royal Society, June 21st, 1838, and printed in the 'Philosophical Transactions' a few months later. The refracting stereoscope is described by Sir David Brewster in a paper 'On the Law of Visible Position in Single and Binocular Vision, and on the Representation of Solid Figures by the Union of Dissimilar Plane Figures on the Retinæ,' which he communicated to the Royal Society of Edinburgh in January, 1843. He further explained and defended his views in subsequent papers, which, like the former, appeared in the 'Edinburgh Transactions' of that and following years. The opinions of Sir David Brewster are further set forth in his work 'The Stereoscope' (8vo, 1856); those of Mr. Wheatstone must be sought in the paper already referred to, and in another which formed the Bakerian Lecture of the Royal Society for 1852, being 'Part II. of Contributions to the Physiology of Vision, and on Binocular Vision.'

The dissimilarity of the pictures, as seen by each eye separately, does not appear to be a modern discovery. It was recognised by Euclid 2000 years ago, and minutely described by Galen. The idea was revived by Baptista Porta in 1593; also by Leonardo da Vinci; by Aguilonius, in a work on the vision of solids (1613); by Harris, in 1775; by Dr. Smith, Dr. Porterfield, and others. Thus, as Brewster remarks, writers in every age knew the two facts that the pictures on the retinæ of the two eyes were dissimilar, and that by the union of these two flat distinct pictures we obtain the vision of solids. But in order to obtain accurate pictures of objects as seen by each eye, and the method of uniting them, photography and the binocular camera were required. The first was already sufficiently advanced, and the latter was introduced by Brewster; while, in order to view the pictures with effect, the lenticular stereoscope was contrived. The first instrument of this kind was constructed by the late Andrew Ross for the inventor, and was exhibited to the British Association in Birmingham in 1849. It did not, however, attract attention until the French optician Du Boscq showed his remarkable collection of stereoscopic views in the Great Exhibition of 1851, after which the demand for the stereoscope warmed into a passion which has scarcely since cooled down. The lenticular stereoscope, as described by the inventor, "consists of a pyramidal box of wood or metal, or any other opaque material, blackened on the inside, and having a lid for the admission of light when the pictures are opaque. The box is open below, in order to let the light pass through the pictures when they are transparent. Another lid is sometimes added, so as to open externally on the bottom of the box, for the purpose of exhibiting dissolving views in the stereoscope. The bottom of the box is generally covered with ground-glass, the surface of which ought to be very fine, or very fine-grained paper may be used. The top of the box consists of two portions, in one of which is the right eye-tube, containing a semi-lens, or quarter-lens, and in the other the left eye-tube, also containing a semi-lens or quarter-lens. These two portions may be advantageously made to approach or recede, in order to suit eyes at different distances from one another; and the tubes containing the lenses should draw out, in order to suit long- and short-sighted eyes." The two dissimilar pictures (which, for convenience, are mounted on a thick card, forming the universally known "slide") are placed in a groove in the bottom of the box, when, on looking through the eye-tubes, they are seen united into a single picture, and the object or objects, if a proper amount of light is obtained, stand out with an almost magical appearance of relief and solidity. For opaque slides, a mirror may be used, and made to move on a hinge, so as to throw light into the instrument. The employment of photography for the stereographs has wonderfully extended the range of the instrument.

The quarter- or semi-lens may also be used in the binocular camera. And here we may state the advantage of dividing the lenses. Whole lenses were originally used; but as the outer half of each lens is useless, as the eyes only look through the inner halves; moreover, as it is impossible to give two lenses precisely the same focal length and magnifying power, it was found to be more accurate, and even cheaper, to cut each lens into halves or quarters, and to shape each half or quarter into a round disc, with the thin part of each turned inwards in the instrument. In this way a single lens could be made into one semi-lens or two quarter-lens stereoscopes. It is evident that these portions, cut from the same lens, must have the same focal length and magnifying power. It is by means of these semi- or quarter-lenses that the stereoscopic effect is produced, though they do not themselves produce that effect. What they accomplish is the transference of the two dissimilar pictures or stereographs to a middle point. The union of these two pictures, or their superposition on that middle point, produces the stereoscopic effect. [SIGHT.] The half- or quarter-lenses are placed 2½ inches apart, corresponding to the distance between the eyes.

Among the various forms of the instrument, we may mention Smith and Beck's *achromatic* stereoscope; the *reflecting* stereoscope; Claudet's *stereomonoscope;* and Skaife's *pistolograph*, consisting of a combination of lenses of small size (one inch in diameter, and the focal length of the combination one inch). In this last instrument the thickness of the glass through which the light passes is small, and hence the actinic rays are so powerful that a photograph may be taken almost in an instant, and is not liable to the errors which the use of large lenses occasions. The small pictures, or *pistolograms*, as they are called, may be magnified by an enlarging camera. The small picture may also be inclosed between two plates of glass, and raised to a temperature sufficient to fuse the three glasses into one, effectually protecting the picture from the presence of the air, and forming what is called a *chromo-crystal*.

From what has been said, it will be gathered that the truthfulness of the stereoscopic picture must depend mainly on the character of the dissimilar pictures or stereographs. Stereographic portraits are usually taken with cameras contrived for the purpose. In order to take stereographs of landscapes, buildings, statuary, &c., the ordinary landscape camera is employed; the camera being removed, after the first picture is taken, to a position parallel to that just occupied, and at an equal distance from the principal object, but more or less distant from the first position in proportion to the distance from the object to be represented. The stereoscopic angle, as it is called, has been laid down at 1 in 25 for objects 50 feet or more distant; some have even recommended that the camera should be removed to a distance of 4 feet in order to take views of an object only 20 feet distance. But the effect of such an arrangement is obviously to make one picture represent much more of the right side, the other more of the left side, of an object falling within the field of vision, than could be seen by a person standing, say midway, between the two positions. And the two pictures so taken must, when united in the stereoscope, present an exaggerated and therefore untrue representation. In fact there will be, what is so commonly seen in the stereoscope, an unnatural appearance of separation between the chief object and the accessories. You see round the figure in fact, just as in life you see round a statuette or small model; and hence there arises that detached model-like appearance which is often, and very properly, objected to in stereoscopic representations. What the stereoscope ought to show is, the representation of an object or objects in nearly the same relative solidity, relief, and separation as the reality possesses; and that is what the stereoscope would exhibit if the stereographs were taken, as they ought to be, and as the most successful (though not the most popular) are taken, from positions little, if at all, exceeding that of the eyes apart. The great importance of strict accuracy in views of countries beyond the reach of the ordinary traveller, of antiquities, objects of special scientific and archæological interest, &c., will be at once acknowledged; and the value of the stereoscope for affording such representations in their greatest attainable perfection is daily becoming more apparent.

STEREOTYPING. [PRINTING.]

STERLING, a word applied to all lawful money of Great Britain. In Ruding's work on 'Coinage,' vol. i., p. 13, 4to. edit., the various supposed derivations of the word are given. Ruding says, "its origin and derivation are still unsettled;" but he inclines to attribute it to an abbreviation of Esterlings, people of the north-east of Europe, some of whom were employed in the 12th century in regulating the coinage of England. But, looking at the facts that *sterling* meant a *penny*, not a species of coinage; that it was used in Germany, and in Scotland before Eastern coiners were employed in England; that it is spelt *starling* by some, as by Spelman, and *estellin* by some of the French writers, we reject the derivation above, and agree with Polydore Vergil and Bishop Nicolson in deriving the name from the *little stars*, which were very common on the penny coins. (See the *Companion to the Almanac* for 1856.)

STERLING'S RULES (or Simpson's Rules). Useful formulæ used principally in estimating the "displacement" of a ship when afloat. They are derived from the equation to the parabola, and have been already noticed under SHIP.

STERN. [SHIP.]

STERNUTORIES, called also Ptarmics, agents which cause sneezing. The most familiar are snuffs of different kinds, many of which cause likewise a flow of the natural secretion from the nose, when they are termed errhines. [ERRHINES.] Sternutories are chiefly employed to occasion a violent succussion of the frame, either to restore suspended respiration, as in some cases of fainting, or to dislodge some foreign body from the nasal passage or windpipe, or more rarely to cause the bursting of abscesses in the tonsils. They are also used to avert impending fits of hysteria or epilepsy, or to terminate prolonged hiccup. Their use requires caution in individuals disposed to apoplexy or affected with rupture. They are generally improper for pregnant women and young children. They occasionally excite too violent and continued sneezing, which may be controlled by creasote; breathing diluted carbonic acid; putting a sinapism round the throat; or inhaling chloroform.

STETHOSCOPE. [AUSCULTATION.]

STEWARD, LORD HIGH, OF ENGLAND; one of the ancient great officers of state. Under the Norman kings and the early kings of the Plantagenet line it seems to have been an hereditary office. Hugh Grentmesnil held the office in the reign of Henry II., and it passed with his daughter and co-heir in marriage to Robert de Bellomont, who was Earl of Leicester. Robert's son held it, on whose death without issue it passed to the husband of his sister, the elder Simon de Montfort, who had also the dignity of Earl of Leicester. From him it passed to his son, the second Simon de Montfort, who was slain at the battle of Evesham in 1265. This high dignity then reverted to the crown, but was immediately granted to Edmund, king Henry the Third's younger son, together with Montfort's earldom of Leicester, in whose descendants, the earls of Lancaster and Leicester, it continued, and in the person of Henry the Fourth, who was duke of Lancaster, was absorbed into the regal dignity.

From this time no person has been invested with this high dignity as an heritable possession, or even for his own life, or *quamdiu se bene gesserit*; but only for some special occasion, the office to cease when the business which required it was ended; and this occasion has usually been when a person was to be tried before the House of Peers. Before this court a peer may be impeached for treason, felony, misprision of treason, and misprision of felony; but a commoner only for high misdemeanors, and not for any capital offence. The lords are summoned to appear, and the decision is by a majority, but no conviction can take place unless the majority consist of twelve or more. The spiritual lords may be present at the trial, but cannot vote. On such occasions there is a lord high steward created, who presides, and when the proceedings are closed, breaks his wand, and dissolves the court; but if the trial take place during the session of parliament, though a lord steward is appointed, it is not considered as his court, he having none of the functions of the judge, only voting with the rest as a peer, although he presides.

STIBDIAMYL. [ORGANOMETALLIC BODIES.]

STIBETHYL. [ORGANOMETALLIC BODIES.]

STIBMETHYL. [ORGANOMETALLIC BODIES.]

STIBTRIAMYL. [ORGANOMETALLIC BODIES.]

STILBENE. ($C_{28}H_{12}$) A crystalline hydrocarbon produced by the distillation of the hydride of sulphobenzoyl. *Thionessale* ($C_{28}H_{10}S_2$), another white crystalline body, is also produced at the same time.

STILBESOUS ACID. A product not fully investigated, obtained by the action of chlorine upon essence of bitter almonds.

STILBIC ACID. [STILBYL.]

STILBYL. ($C_{28}H_{11}O_4$). The hypothetical radical of a small group of organic compounds of which the following are the names and formulæ :—

Benzöin or hydride of stilbyl	$\left.\begin{matrix}C_{28}H_{11}O_4\\H\end{matrix}\right\}$
Benzile	$C_{28}H_{10}O_4$
Benzilic acid, stilbylic acid, or stilbic acid .	$\left.\begin{matrix}C_{28}H_{11}O_4\\H\end{matrix}\right\}O_2$
Chloride of stilbyl	$\left.\begin{matrix}C_{28}H_{11}O_4\\Cl\end{matrix}\right\}$

STILBYLIC ACID. [STILBYL.]

STILL. [DISTILLATION.]

STILLISTEARIC ACID. A crystalline organic acid obtained by the saponification of the vegetable fat expressed from the fruit of the *Stillingia sebifera*.

STIMULANTS or *Excitants* (in medicine), agents which increase vital action, first in the part to which they are applied, then of the system generally, and perhaps ultimately of some particular organ; and when this organ is a gland or secreting organ, a renewed or augmented secretion is observed. The nervous system seems to be the part which they chiefly influence, and through it the vascular, and in many cases the muscular. This is well seen in the simple effect following the employment of ammonia in a fainting fit, where the application of the vapour of ammonia, or its carbonate (smelling salts) to the nostrils, stimulates the brain, and so restores the heart's action, by which the circulation is resumed, and all parts dependent on it vivified. Aromatic vinegar, electricity, galvanism, and the sudden application of cold, especially alternated with heat, and chloric ether, have a like effect.

The agents which constitute this class, though often confounded with others, are perfectly distinct; differing from all by their sensible qualities, their chemical composition, the nature of their physiological effects, and of the therapeutic indications they are calculated to fulfil. They are often confounded with tonics [ANALEPTICS], antispasmodics, and even narcotics, to all of which they have relations of affinity, but are not identical with any. In so far as they both act on the nervous system, they have most affinity with antispasmodics [ANTISPASMODICS], but differ from them inasmuch as stimulants increase the actions which are natural to the different organs of the body; while antispasmodics allay or diminish inordinate or abnormal action. Nearly the same may be said of the distinctions between them and narcotics [NARCOTICS], for though the increased action excited by an agent of this class, if extreme or long continued, is followed by a greater or less degree of collapse, still this is very different from that which follows the employment of a narcotic, which is much greater, as well as more speedy. Certain articles, such as opium and alcohol, may be made to act in either way; but while opium is not unfrequently used to stimulate, alcohol is never used medically as a narcotic, though the coma and stupor which ensue from an excessive dose of it are as profound, and often as fatal, as from an overdose of opium.

Above all, stimulants are most frequently confounded with tonics; but independently of the consideration that stimulants operate directly on the nervous system, while tonics affect the muscular and sanguiferous systems, their operation, as well as the nature of their effects, is entirely different. Stimulants render the movements generally more frequent; tonics render them stronger; stimulants too freely or too often used, exhaust the excitability; tonics, within a certain limit, maintain it. The action of the one is immediate and transient; that of the other slow, scarcely perceptible, and progressive, but permanent. This is best seen in their effects on the stomach. Tonics render the digestion more perfect; stimulants quicken it: moreover, most tonics must be themselves digested before the system can benefit by them; while stimulants display their effects as soon as they touch the lips or reach the stomach. In many fevers cinchona bark produces no abatement of the symptoms for which it is usually prescribed, as the stomach is too weak to digest it; but capsicum or cayenne pepper given along with it, so rouses the stomach that the febrifuge power of the bark is then manifested.

Stimulants are of two classes: one comprising medicinal substances; the other, warmth, cold, electricity, galvanism, and mental agents, such as music (when lively), joy, hope, &c. Many of the latter class have been already treated of [BATHING; ELECTRICITY; GAL-

VANISM]; of the others, the effects are too familiar to require notice, except to recommend the practice of encouraging the hope of a favourable issue to his complaint in the mind of a patient, in all cases not desperate, as cherishing this feeling greatly increases the chance of recovery. The former class is divided into permanent stimulants and diffusible stimulants, the effect of the permanent being slower but more lasting, that of the others quick but transient. The first are used where a considerable and enduring power is wished to be imparted to the system, as in the convalescence from acute diseases, the other where some great and impending danger is to be obviated, as in cases of fainting fits, or when sedative poisons are to be antagonised. In these latter instances, ammonia, alcohol in some form, or sulphuric ether, are commonly had recourse to. Permanent stimulants are generally volatile or essential oils, pure, or in the combinations in which they exist in roots, barks, or flowers, and are often highly aromatic; malt liquors may also be classed with permanent stimulants. The precise stage in the progress of fevers and other acute diseases, when antiphlogistic or reducing measures should be abandoned, and stimulants substituted, is the nicest point that a medical attendant is ever called upon to decide; and nothing more clearly distinguishes the judicious practitioner than his correct determination of this point. It may be safely asserted that more cases are lost by a premature use of them than by delay, as the numerous relapses in fever testify. All persons recovering from severe diseases are almost in the condition of newly born children, in whom the irritability and excitability are very great. These should not be violently acted upon, but on the contrary they should be treated with the utmost gentleness and care. Sleep is a more useful restorative than any other. Stimulants are more necessary during the night than during the day, and as more persons die during that period, the use of stimulants becomes more urgent at that time. But the best and most harmless is a very strong infusion of tea, especially green, given in small quantities, every hour or two, as the danger of the case may point out.

A useful stimulant is furnished by coca, the leaf of Erythroxylon coca (Lamarck), a shrub native of South America. Its power of enabling the Indians to sustain prolonged fatigue, either on journeys or while working in mines, has been long known. It has only lately been tried in Europe. Its utility seems manifest in cases of nervous exhaustion from over-study or long fasting. A few grains chewed, or an infusion of varying strength according to the necessity of the case, wards off fatigue and assists respiration. But too much caution cannot be observed, lest a habit should be acquired, not less pernicious than the abuse of opium or alcohol. (See Pöppig's *Travels in Peru*, an extract from which is in *Companion to Botanical Magazine* vol. i., p. 161, and with *fig.* vol. ii., p. 25; Weddell's *Voyage dans le nord de la Bolivie;* Johnston, *Chemistry of Common Life*, vol. ii., p. 137, and *The Technologist*, vol. i., p. 255.)

STIVER. [Money.]

STOCKADE, in Fortification, is the name given to a wall constructed by planting upright in the ground squared trunks of trees, or rough *piles* of timber, so as to enclose an area which is to be defended. The trunks or piles are planted close together; and at intervals of three feet from one another loopholes are cut through them, or notches a few inches long are cut down, vertically, from the top, through which the defenders may direct a fire of musketry on the assailants. An inclosure of timber so planted is sometimes called a *Palanka*, from a name which is said to have been given by the Turks, when they first entered Europe, to their field-redouts or small entrenched camps.

Stockades are still frequently constructed as temporary fortifications in countries which abound with timber, as in North America and the East Indies; and among uncivilised nations, these, and rude parapets of earth, are the only kinds of fortification which have been executed. They were also, in general, the means employed by ancient armies while besieging towns, to protect themselves or to prevent the escape of the garrison. The walls with which the Peloponnesians surrounded Platæa during the siege and the blockade of that city were stockades, consisting of palisades planted close together in a double line with a certain interval between the lines. (Thucydides, ii. 75.)

The description of the pahs, or hippahs, of New Zealand, given in the accounts of Captain Cook's voyages, would nearly serve for the stockades within which the natives of that country have on several recent occasions resisted the assault of a British force. It is stated that the works consisted of trunks of trees planted close together, with a small inclination towards the interior space; and that at intervals from one another, particularly at the angles of the works, there were scaffolds whose heights from the ground were three feet less than that of the top of the wall, so that the defenders were able to see the ground at the foot of the wall while they were concealed from the view of the enemy. In the interior there was usually a hollow place, in which the women and children, with the provisions, were deposited. The pahs are generally on the summits of heights, and they are sometimes strengthened by outworks of a similar nature. Those of most recent construction are usually so placed as to allow of a ready retreat into "the bush."

On the frontiers of the United States of North America, during a war, stockades consisting of roughly-hewn trunks of trees planted close together in upright positions and pierced with loop-holes for musketry, are very frequently constructed for the purpose of inclosing an area which is to be defended; and at each of the angles of the inclosure a sort of blockhouse, serving as a bastion to flank the stockade, is constructed with very thick logs of timber placed horizontally: these block-houses are sometimes formed with an upper story, the angles of which project over the sides of the lower one, so that by loop-holes in the projecting part of the floor a fire of musketry may be made upon the enemy when at the foot of the wall.

STOCKINGS. [Hosiery Manufacture.]

STOCKS, a term applied to the various "Funds" which constitute the national debt. Each proprietor of stock may transfer his interest to others by sale. When the transfer is effected by a broker he must be authorised by a power of attorney from his principal, the stamp-duty on which is 21*s.* 6*d.*; and the document may be so drawn as to empower him both to buy and sell stock and to receive the dividends for the person by whom he is commissioned. Few persons buy or sell stock except through the medium of a broker, but the general practice is to receive their dividends themselves. The purchaser acquires the dividend due upon the stock for the current half-year, and thus at one point there will be a sum of 29*s.* 4*d.* due on three per cent. stock, and a fortnight afterwards only 1*s.* 8*d.* On the bargain being completed, the parties repair to the Bank to transfer the stock. "For this purpose the seller makes out a note in writing, which contains the name and designation of the seller and purchaser and the sum and description of the stock to be transferred. He delivers this to the proper clerk, and then fills up a receipt, a printed form of which, with blanks, is obtained at the office. The clerk, in the mean time, examines the seller's accounts; and if he find him possessed of the stock proposed to be sold, he makes out the transfer. This is signed in the books by the seller, who delivers the receipt to the clerk; and upon the purchaser's signing his acceptance in the book, the clerk signs the receipt as witness. It is then delivered to the purchaser upon payment of the money, and thus the business is completed." (Dr. Hamilton, 'History of the National Debt.')

Bargains in stock are transacted in the Stock Exchange, in Capel-court. All the more respectable brokers are members of the Stock Exchange, into which association they are elected annually by ballot; but many of the jobbers, who are not members and carry on their transactions outside the exchange, are said to be persons of wealth. The governing body consists of a committee of twenty-four, also elected by ballot. The established rate of brokerage is one-eighth per cent. (or 2*s.* 6*d.* in the 100*l.*) upon the amount of stock transferred.

The dividends on all descriptions of stock are due half-yearly, either on the 5th of January and 5th of July, or on the 5th of April and 10th of October, and are paid about a week afterwards; and for about six weeks previously, the books at the Transfer Office being closed, transfers cannot be regularly made. The transfers on each stock are effected at other times only on certain days in the week, which may be ascertained by a reference to any almanac.

The bargains for *time* form a very important portion of the business of the Stock Exchange. They are bargains to deliver stock on a certain day at a certain price, the seller of course believing that the price will fall, and the buyer that it will rise. When the period for completing the bargain has arrived, a settlement is usually effected without any payment of stock, the losing party simply paying the difference. "These bargains are usually made for certain days fixed by a committee of the Stock Exchange, called *settling days*, of which there are about eight in the year, namely, one in each of the months of January, February, April, May, July, August, October, and November; and they are always on Tuesday, Wednesday, Thursday, or Friday, being the days on which the commissioners for the reduction of the national debt make purchases. The settling days in January and July are always the first days of the opening of the bank books for public transfer; and these days are notified at the bank, when the books are shut to prepare for the dividend. The price at which stock is sold to be transferred on the next settling day is called the price *on account*. Sometimes, instead of closing the account on the settling day, the stock is carried on to a future day on such terms as the parties agree on. This is called a *continuation*." (Dr. Hamilton.) A defaulter, in the language of the Stock Exchange, is termed a "lame duck," and his name is posted for a certain time in the great room. The sellers of time bargains are also technically called "bears," and the buyers "bulls;" the interest of the former being to beat down prices, and of the latter to raise them.

Stock of a high denomination may usually be bought cheaper than that of which the nominal interest is lower; and it is therefore the most advantageous for temporary investment. There is always a probability that the stock bearing the highest rate of interest will be reduced by the government when a favourable occasion presents itself; but the price of any one stock may be taken pretty nearly as an indication of the prices of the rest. The fluctuation in the price of stocks generally may be traced to an almost infinite variety of causes—to the abundance or scarcity of money, and the opportunities of employing it to advantage in mercantile speculations; to the rumours of a new loan, or of the imposition of a fresh tax, or even the repeal of a tax; to rumours of war; and to innumerable other circumstances relating to the trade, finance, and other domestic affairs of the country. In 1797 the Three per Cents. were reduced to the lowest point which they have ever reached (47⅞) by the success of the French armies, combined with adverse circumstances at home.

Besides the English funds, shares in many descriptions of foreign stocks, which have been created by loans raised in this country, are constantly for sale in the money-market, as are also shares in railway, canal, mining, and numerous other similar speculations.

STOCKS, in Horticulture, are young trees which are designed for the reception of the grafts or buds from other trees. The process by which a part of one tree is transferred to another is called grafting or budding [GRAFTING], and the object attained by it in gardening is the securing the continuance and multiplication of an individual plant that may possess peculiarities deemed worthy of preservation. It is by this process that the great number of varieties of cultivated fruits are preserved with remarkable integrity, and by which a constant improvement may be ensured.

Stocks are for practical purposes divided into three kinds: crab stocks, free stocks, and dwarf stocks. Crab stocks are those which are grown from the seeds of wild and ungrafted trees, as the cherry, plum, apple, &c. These stocks are commonly used where a large and hardy growth is desirable. In the selection of wild stocks, those which grow cleanest, and are freest from irregularities of the stem and defects in the bark, should be chosen. Free stocks are those which are raised from the seeds or layers of fruit and orchard trees which have been grafted. These stocks are found desirable when the object of grafting is to obtain choice varieties of apples, peaches, nectarines, apricots, or plums. Dwarf stocks are those which are raised from low-growing shrubby trees. They are used in the grafting of low-standards for small gardens, also for wall-trees, and espaliers.

Stocks are raised in nurseries from seeds, suckers, layers, and cuttings. When raised from seeds, they should be sown in the autumn, in beds of common light earth: all lateral branches should be cut off as they grow up; and, according to circumstances, they will be fit for grafting in one, two, or three years. Stocks may be used when they have attained the size of a goose-quill, up to that of a man's finger. When stocks are wanted expeditiously, they may be produced from suckers taken up and planted in the autumn, when they will be ready for use the following July or August. They are not often raised from layers and cuttings.

In the selection of stocks, not only is care required that they be of the same kind as the graft or scion, but that there is a proper relation between the rapidity of their growth according to the objects wished to be attained. When the growth of the scion is more rapid than that of the stock, it will sometimes die. This is the case with peach-trees budded on plum-stocks and pears on the hawthorn. At the same time, when trees are naturally too luxuriant in leaves and branches, they may be dwarfed in their growth and made fruitful by placing a scion from them on a stock that grows slower than themselves. In this way apples may be dwarfed by being grown on paradise, pear, or quince stocks.

It is frequently desirable to select those stocks which are hardier than the scion, for the purpose of ensuring the growth of the latter. Not that the stock has any power of communicating hardiness to the scion; but those stocks that are accustomed to colder latitudes will supply a sufficient quantity of sap, and be able to resist the influence of a decrease of bottom heat. The kind of soil in which a stock grows has also much to do with its being adapted for the growth of certain scions. Thus the crab has been found best for the apple, the wild pear for the cultivated pear, the almond for the plum, and the mahaleb for the cherry, on chalky soils. But the stock also has the power of deteriorating the fruit; the austere plum and the crab will not improve the peach or the apple of the scion which may be grafted on them. Some gardeners therefore recommend stocks of what they term an ennobling character; that is, of a species as good as that of the scions they are to bear. Apricots, currants, and gooseberries are stated to have been greatly improved by this process.

STOCKS, a wooden machine formerly much used for the punishment of disorderly persons by securing their legs. The time when they were first used in England does not appear; but in the second Statute of Labourers, 25 Edw. III., 1350, in the octave of the Purification, it is enacted that refractory artificers shall be put in the stocks by the lords, stewards, bailiffs, or constables of the towns where their offence has been committed, by three days; or sent to the next jail, there to justify themselves; and that stocks be made in every town for such occasion between that time and the feast of Pentecost. ('Rot. Parl.,' ii., 234.) In 1376 the commons prayed the king for their establishment in every village. (Ibid., 341.)

In 'King Lear,' act ii., sc. 2, Shakspere has introduced the stocks upon the stage. Farmer, commenting upon the passage, says: "It should be remembered that formerly in great houses, as still in some colleges, there were moveable stocks for the correction of the servants." The stocks are still to be seen in some country places, and are not wholly disused.

STOLE, originally a long vestment, a matron's robe, from the Latin *stola*, and that from the Greek στολή. Pitiscus, in his 'Lexicon Antiquitat. Roman.,' has a long article upon the *stola*, as worn by the ancients.

In later times stola was the term more particularly applied to a broad strip of cloth or stuff, with three crosses upon it, worn by priests of the Romish church as a sacerdotal vestment, with whom it was also called *Orarium*. "Orarium est stola," says Lyndwood, in his 'Provinciale,' "qua sacerdos in omni obsequio divino uti debet, et suo collo imponitur ut significet se jugum Domini suscepisse."

The stole or orarium, according to Palmer ('Origines Liturgicæ,' vol. ii.) has been used from the most primitive ages by the Christian clergy. It is spoken of by the first council of Braga, A.D. 563; by Isidore Hispalensis, A.D. 600; the Council of Laodicea, in Phrygia, A.D. 360; Severianus Gabalitanus, in the time of Chrysostom; and many others (see Bingham's 'Antiq.,' b. xiii., c. 8, § 2; and Gerberti, 'Liturg. Aleman.,' tom. i., p. 240); and it has been continually used by all the churches of the west and east, and by the Monophysites of Antioch and Alexandria. "The stole," says Palmer, "always called Ὠράριον by the Greeks, was fastened on one shoulder of the deacon's albe, and hung down before and behind. The priest had it over both shoulders, and the two ends of it hung down in front. The Eastern churches call the stole of the priests ἐπιτραχήλιον. Thus simply were the dresses of deacons and priests distinguished from each other in primitive times."

The pall of the metropolitans was originally only a stole wound round the neck, with the ends hanging down behind and before.

That the word 'stole,' in the sense of a sacerdotal vestment, was of early adoption into the English language, appears from the 'Saxon Chronicle' under the year 963, when Archbishop Dunstan, at the time of personally confirming King Edgar's grant of lands to the monastery of Peterborough, added that he himself gave, among other vestments, his *stol* to St. Peter.

STOMACH, DISEASES OF THE. The tissues of the stomach may be the seat of various pathological states, producing symptoms which are often referred to the general head of dyspepsia. [DYSPEPSIA.] This diseased condition is, however, but a general term for the expression of a variety of symptoms arising from the pathological conditions of the organ. The morbid states of the stomach have been recently studied with great care, by the medical men both of this country and the continent. The principal structural morbid conditions of the stomach to which attention need be drawn are: 1. Softening. 2. Degeneration. 3. Congestion. 4. Inflammation. 5. Ulceration. 6. Cancer. At the same time a variety of symptoms come on indicative of a change in the functions of the stomach, and which may occur quite independent of any of the above structural derangements. Amongst the most remarkable of these functional derangements are the following:—

1. *Vomiting*, which may come on from a disordered state of distant organs, as of the brain, liver, lung, uterus, testicle, and other parts. This symptom is produced by the reflex action of the nervous system. In the majority of instances in which vomiting occurs, it is produced by the morbid condition of some other organ. It should, therefore, always lead to the investigation of other organs, as attempts at arresting it will not be successful till the cause is removed.

2. *Deficient secretion of Gastric juice.*—Many dyspeptic symptoms are directly traceable to this cause. It is accompanied with a sense of weight and oppression at the pit of the stomach. The food remains undigested in the stomach, and frequently decomposes, giving to the breath an unpleasant smell. This state requires for its treatment the administration of stimulants of the gastric function. Hydrochloric acid increases the secretion of the gastric acid, and pepsine, the active principle of the gastric juice, has been recommended as a remedy.

3. *Fermentation of the Food.*—The food may be variously decomposed according to the state of the stomach, and sometimes one change comes on and sometimes another. Without any apparent cause in the stomach itself, a fermentation comes on in the food, attended with the development of a large quantity of carbonic acid gas, and which is also accompanied with the presence of a minute plant, first discovered by Professor Goodsir of Edinburgh, and called by him the *Sarcina Ventriculi*. This state comes on when distant organs are affected, or in a general state of the system which must be attended to for cure.

4. *Indigestion*, or any derangement of the function of digestion, dependent on morbid states of other organs, either connected with the stomach, as the salivary glands, the liver, the pancreas, or the bowels, or upon derangement of organs more distant, as the kidneys, brain, &c., or upon gluttony or drunkenness. This functional derangement is cured by the removal of the cause. [DYSPEPSIA.]

The general characters of the structural diseases of the stomach are as follows: *Softening* of the mucous membrane of the stomach may occur during life as the result of the action of the gastric acid upon the membrane, or it may occur from the same cause after death. The latter form is very frequent, and was formerly regarded as an indication of structural change during life. Softening of the stomach occurs during life in wasting diseases, in which there is a great depression of the vital powers, as in typhoid fever, cancer of the womb, peritonitis, and tubercular disease of the brain. It more frequently occurs in the latter disease among children, than in any of the diseases of adults. This disease is accompanied with great disorder of the digestive functions, pain and tenderness of the epigastrium, loss of appetite, thirst, vomiting, and nausea.

Degeneration occurs in the glandular structure of the proper mucous substances of the stomach, and is the most common of the structural diseases of the stomach. In these cases either the gastric follicles are entirely destroyed, or the cells in their interior become changed, or the tissue between the follicles is charged with fibrinous and other deposits. This state is attended with severe dyspeptic symptoms, nausea or vomiting in the morning, oppression after food, and frequently anæmia and general debility. This morbid state may prevent altogether the digestion of food in the stomach; but the digestive functions of the intestines may become more active, and the general nutrition of the body must suffer. It is not however unfrequently the case that the intestinal mucous membrane is affected in the same way as the stomach, and then the general symptoms become more severe. In the treatment of these cases the object should be to relieve the stomach of its digestive duties as far as possible. Albuminous food should be taken in small quantities and frequently. The carbonates of soda and potash may also be advantageously employed so as to facilitate the passage of the food out of the stomach before digestion commences.

Congestion of the blood-vessels of the stomach occurs as the result of any mechanical impediment which prevents the blood returning from the stomach towards the heart. It occurs in disease of the liver and spleen, and leads to the deposit of melanic matters in the mucous membrane, and to degeneration of the tissue. One of the consequences of such congestion is the effusion of blood into the stomach, and its ejection by vomiting. This disease is called *hæmatemesis.* In the treatment of this form of disease efforts must be made to remove its causes. Astringents, as sulphuric acid, tannic acid, and acetate of lead with opium may be given. Sometimes congestion of the stomach occurs as the result of the suppression of some natural discharge.

Inflammation of the stomach or gastritis is a very rare disease. It is commonly seen as the result of the introduction of poisons into the stomach, and also from the excessive use of alcoholic beverages. When it occurs it is accompanied with congestion. It is attended with vomiting, excessive thirst, and the ejection of a fluid like that found in pyrosis. [PYROSIS.] In treating this form of disease all stimulants must be avoided. Food of the mildest and most easily digested kind must be administered, and leeches may be applied to the epigastrium. Iced water and lumps of ice should also be freely given.

Ulceration of the mucous membrane of the stomach occurs both in congestion and inflammation. Ulcers may however exist without the symptoms of these diseases. The ulcer is generally solitary, deep, well-defined, of a circular or oval shape, and is about the size of a shilling. It is a dangerous condition and may end fatally by perforating the membranes of the stomach, or by producing hæmorrhage, or excessive exhaustion. Ulceration is accompanied by pain of a gnawing and burning kind a few minutes after the taking of food. There is also great tenderness over the epigastrium, and frequently pain in the back. Vomiting is also a common symptom after taking food. The treatment of cases should be more dietetical than medicinal. Food must be taken in small quantities and of the most digestible kind. Milk with preparations of wheaten flour are to be commended. Astringent medicines should be administered, and the salts of iron may be prescribed with astringents should hæmorrhage supervene.

Cancerous ulceration of the stomach is not easily distinguished from simple ulcer during life, and requires the same treatment. It is not so frequent as is sometimes supposed. Dr. Brinton states that not more than one per cent. of fatal cases of ulceration of the stomach are due to cancer. Cancerous ulceration is most frequently seated at the orifices of the stomach.

STONE. [CALCULUS.]

STONE FOR BUILDING. There are few practical questions belonging to the building arts of more importance than those connected with the nature of the stones used in them; for not only does the character of the architecture adopted materially depend upon the facilities the stones present for artistic expression, but the durability of the buildings, and the retention of their original effect must be regulated entirely by the powers of resistance of those materials to the causes of decay which are always at work upon them. Where stone of large dimensions, and of great transverse strength, is used habitually, architecture assumes an imposing palatial effect, with a tendency to prefer the horizontal to the vertical line: where stone of small dimensions is used, vaulted construction, heavy piers, and the minute style of ornamentation (which always accompanies the use of the rendering coats, almost necessarily used on such stones,) may be as distinctly traced as the external characteristics of the architecture adopted; and the horizontal line habitually disappears in favour of the arch, or of the vertical line: where stones are easily worked, florid ornamentation is adopted; where they are hard, and comparatively unmanageable, massive, and sometimes clumsy forms are adhered to. The durability of the stones, and their capacity of supporting fine sculpture, moreover, must materially affect the decision of the architect with respect to the amount of decoration to be employed on them, and to the choice of the mode in which they are to be treated; for it must evidently be absurd to spend time and money on the decoration of materials which are susceptible of rapid or of unequal decay. The resistances of stones to crushing forces have likewise a marked influence upon the style of building they are capable of receiving; for that style is often light, or massive, in proportion to the resistance, provided always that the labour in the conversion of the stone should offer little resistance to what may be called its plastic treatment. The colour of stones has also an influence upon the æsthetical effect of a building; and it, therefore, becomes in its turn a matter of importance to the architect, both on account of the original colour, and of its possible modifications.

A good building stone must possess, then, great powers of resistance to crushing, and breaking, weights; it must be even in its grain, and able to furnish large blocks; it must not contain elements which are susceptible of decomposition by reason of the atmospheric action upon them, or of their mutual reactions upon one another; it must be non-absorbent of water, or of vapour, to a certain extent (but only to a certain extent, as will be shown in the sequel); and, as far as possible, be of a homogeneous nature. As a general rule, the denser stones are more durable than the lighter ones; but this law only holds good when their structure is of a permanent and of a crystalline nature. The stones which are of a massive character from top to bottom of the quarry-bed are usually more durable than the foliated, or fissile materials of the same description; and the crystalline stones are almost always superior to the amorphous ones, both in appearance and durability. The granites, quartz rocks, and transition marbles furnish the most lasting building stones, though even they are occasionally subject to destructive actions of peculiar natures; the sandstone conglomerates, and the sandstones partially metamorphosed by the vicinity of plutonic rocks, are usually more durable than the limestones; whilst of the latter, the stones presenting a regular crystallisation are far superior to the saccharoid marbles, or to the amorphous earthy-textured stones. The clay slates, which perhaps can hardly be considered to be building stones, present singular powers of resistance to atmospheric agents, after they have been exposed to the action of plutonic rocks; and the magnesian limestones, when selected from the crystalline varieties, are of great practical value. When stones are mainly composed of organic remains united by a more or less crystalline cement, or when they are composed of materials having different rates of expansion, there are great probabilities of the occurrence of rapid decay, and materials of this description should be avoided for external uses.

In the article ATMOSPHERIC INFLUENCE will be found a short review of the present state of our knowledge with respect to the resistance of building stones to the particular causes of decay presented by that agent. There are other causes occasionally at work, however, to which it may be advisable to call attention, for the stability of a building may often depend on their action. Thus in bridges, it is found that some stones do not satisfactorily resist exposure to tidal immersion, though they may stand, as workmen say, very well when kept constantly either wet or dry; the Portland stone is an illustration of this remark. Other stones again may stand well in fresh water, but they disintegrate in salt water; others may stand well in the atmosphere of the interior of a country, and yet yield rapidly on the sea shore, or in certain towns. Some stones resist the action of fire, such as the commonly-called fire-stones of the subcretaceous series; whilst the limestones, and the ordinary sandstones, are very injuriously affected by great heat; and are either partially calcined, or split and cracked by it in a manner to destroy their powers of cohesion. Where the stones employed are intended to receive heavy crushing loads, they must be selected from amongst the denser varieties; and the portions of the stone work of a building which might take up water by capillary action must be executed of such materials as should limit its range and its chemical effect. And here it may be as well to remark that, although in positions of this kind, the non-absorptive powers of a stone are great recommendations for its use, yet that in the plain wall spaces of the upper structures externally, and in floors and wall linings internally, there is a disadvantage in the use of the decidedly non-absorbent stones. They are in fact rapid conductors of heat, and if any moisture should exist in the atmosphere it condenses on their surfaces in a manner which is unsightly, and often injurious to the health of the inhabitants of the building wherein this phenomenon occurs. Some stones are exposed to a very disagreeable action from the efflorescence of the salts they may contain; others again part with their constituents in a manner to compromise the solidity of the mass, and even to produce injury to the materials around them, as for instance, in the case of the magnesian limestone, which under the action of London rain parts with the sulphate of magnesia in such quantities as to destroy, upon its subsequent efflorescence, the materials into which it filters. It would seem, moreover, that some of the limestones are liable to chemical changes of a peculiar nature; for the marbles, such as the Carrara marble, pass from the subcrystalline to the saccharoid state on exposure to gentle heat, or to the effects of the atmosphere; whilst on the other hand, the Portland stone, and other varieties of the carbonates of lime, which have not been affected *in situ* by plutonic agencies, harden by exposure. It may be that in the former case, the water of crystallisation evaporates; and thus allows the base to resume an amorphous character; and that in the latter, the hardening proceeds from the change in the proportions of carbonic acid present, the stones being originally protocarbonates of lime, and subsequently passing into the percarbonates. The best sandstones also harden by exposure to the weather; and it may be observed that this indurating process takes place the most rapidly when the water taken up by the sandstones may contain any lime in solution.

The resistance of building stones to physical forces depends greatly upon the homogeneous nature of their grain, and the direction of their planes of stratification and cleavage; the resistance to disintegration and decay depends also very much on the same causes, especially when the stones are employed in buildings. Thus the stones which have been produced by the deposition of diluvial, or alluvial currents, present distinct traces of bedding, in consequence of the inequalities in the transporting powers of those currents at particular periods; and if those stones should be used in such a manner as to leave the planes of bedding vertical, and parallel to the exposed face of the building, they would be exposed to exfoliation of a very dangerous character. The stones which have been produced by the deposition of substances in suspension in former oceans, such as the oolites, the chalk, and the freshwater, or marine limestones of the tertiary series, often have planes of bedding produced by the periodic abundance of the animal remains they may contain; or they may have distinct laminations in consequence of their mode of crystallisation. In either of these cases the stones would be exposed to crush with greater ease in the direction of the divisional planes, and the effects of the atmosphere would be most energetically exercised when those planes were placed in a direction to favour the absorption of moisture by capillary action, or to allow the stone to exfoliate in a direction parallel to the face. In fact, the most important rule to be observed in the practical use of stone is to place it "in the natural way of the bed," as workmen say; and though there may be some stones in which it is very difficult to distinguish the bed, and others in which there is less reason than usual for adhering to this law, yet even in them it is preferable to place the bed of the stones in its natural position.

A very elaborate report was drawn up in 1839, by a commission named for the purpose of selecting the building-stone to be employed in the Houses of Parliament; but in consequence of the marked failure of the material then selected, the recommendations of that report have lately been treated with neglect. This is unfortunate; because there is much information of value in the report, and the methods of examination it was based upon are substantially correct; and, as it now appears that the stone actually used in the Houses of Parliament, *was not the one recommended by the commissioners*, the latter ought not to be blamed for the failure which has occurred. The errors which, however, do exist in the report consist in these points:—1. The resistances to atmospheric action were appreciated by the state of the stone in certain ancient buildings, which were mostly in the neighbourhood of the quarries from whence those stones had been extracted. 2. In the attempt to judge of the durability of both new and old stones by what is known as Brard's test, or exposing them to the effects of the efflorescence of a solution of the sulphate of soda. Now it is notorious that the atmospheres of large towns contain many elements which do not exist in the atmosphere of the country, and nothing but a long exposure to the former would justify an absolute opinion as to its possible effects; even the Caen stone itself resists tolerably well in Lower Normandy, but it decays rapidly at Hâvre, and more rapidly still in London. The objections raised by the French engineers to Brard's test have already been referred to under ATMOSPHERIC INFLUENCE; and it may suffice here to observe that practically it has been shown to be of very little use as an indication of the durability of a building-stone.

Before closing these remarks, it may be as well to state that some classes of stones are known by the name of *freestone*, when they are susceptible of being worked freely by the axe, or by the mallet and chisel; the ordinary sand and lime stones are of this description, but the granites, whinstones, slates, and basalts, cannot be worked in this manner. Another technical distinction in the mode of conversion arises from the description of saw used; the softer stones are cut by the toothed saw, the harder ones are cut by the plate saw and grit. The marbles are susceptible of receiving a polish; the ordinary sand and limestones remain dull whatever labour may be expended on their faces. The stones which strike fire (or the silicious ones) are usually harder and more durable than the calcareous stones; but the labour upon them is much more expensive; and it is almost always the case that the stones which present on the surfaces of their fracture, a number of asperities and sparkling facettes are more difficultly worked than are the stones which present even, dull faces. Of materials of this description the lighter coloured ones are generally softer than the darker ones, and it may be considered a safe rule in judging of new stones, that if they absorb water easily they are not fitted to resist the action of the atmosphere. If the stones should yield a clear ringing sound, they may be considered to be of a fine uniform texture, and free from flints, earthy nodules, vents, or shakes; and if in working they should emit a sulphurous smell they would usually prove to be durable. One of the simplest and best precautions to be observed in the use of building-stones, is to quarry them some long time previously to their application, and to expose them to the weather, in order that they may lose gradually what workmen call their "quarry damp." In buildings, the denser and harder stone should be used in the lower courses, the lighter ones in the superstructure; the non-absorbent stones should be used in the ground and in plinths, cills, string courses, and weather beds of cornices, &c.; the softer and more absorbent stones may be used for plain walling.

Mr. Hodgkinson found that the resistance of stone columns to crushing weights was nearly uniform when their heights were less than 12 times the dimension of their sides; when their heights were 15 times their sides, the resistance was manifestly diminished; when their heights were 24 times their sides, the resistance diminished in the ratio of 138 to 96 nearly; when they were 30 times the side, the resistance became reduced from 138 to 75; and when they were 40 times their side, the resistance was reduced from 138 to 52. Stone columns are considered by Mr. Hodgkinson to yield first at the ends, in consequence of the tendency of rigid bodies to split into wedges, with sharp points at their apices, under the action of superincumbent weights. The weights stone-columns can bear depend at all times on their smallest section.

Mr. Adie published in the 'Transactions of the British Association for the Advancement of Science,' 1834, some interesting observations on the expansion of stone under the influence of heat. From these it would appear that within a range of 180° Fahr., the expansion of the Craigleith stone is 0·0011758 of its length, or the same as the expansion of glass, and very nearly the same as the expansion of cast-iron, as ascertained by Lavoisier. The expansion of the black Galway marble was found to be 0·00043855 of its length; that of white marble seems to have been rather less. [HEAT; RESISTANCE OF MATERIALS.]

STONEWARE. [EARTHENWARE; POTTERY AND PORCELAIN.]

STONE WORKING. Under QUARRY AND QUARRYING a description is given of the mode of detaching and shaping blocks of stone at the quarries. A few lines will suffice to convey an idea of the subsequent operations.

Until within a comparatively recent period, few other tools than the saw and chisel were employed in this work; but now machinery, moved by steam-power, is extensively adopted. The working of *marble* for ornamental purposes was the chief cause of this change; seeing that the highly-wrought surfaces might suitably be produced by labour-saving expedients. The sawing by hand of blocks of stone for buildings, or slabs for pavements, is familiar to every one. The workman employs a kind of blunt knife, which is converted into a species of saw by the presence of sand and water; the action of this blade, by a process something between cutting and grinding, severs the block of stone into two. The shaping by hand of blocks of stone is equally familiar; chisels, of various shapes, urged by a mallet, do the whole work. But it is of more elaborate contrivances that we here treat.

Some of the marble-sawing machines are of the kind shown in the annexed cut. Several saws are fixed parallel in a frame, at any distance apart according to the thickness of the slab to be cut. The frame slides in vertical grooves; and it is so balanced that the saws are kept at a height corresponding to the part of the block which is being cut, and descend as the cut deepens. These so-called saws are blades of soft iron, used with sand and water; the sand being varied in quality according to the kind of stone to be cut. An apparatus is placed over the frame, whereby a little stream of sand and water is made to flow continuously into each saw-cut. Not only does the use of such a machine save much labour, it saves material also; for in hand-sawing the workmen never succeed in keeping the saw in a true plane; and, as a necessary result, great waste is occasioned in subsequent grinding. Mr. Stewart has recently invented a machine for cutting large masses of stone; a series of chisel-cutters follow each other in the same cut, and are fixed to a frame travelling on a kind of railway. The action of

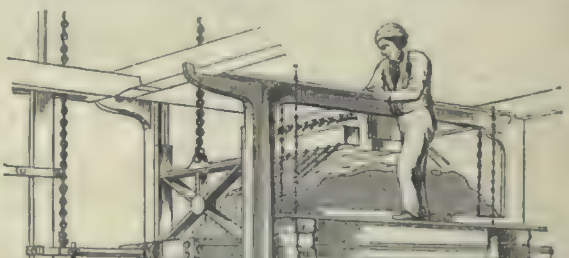

Fig. 1.—Marble Sawing Machine.

each cutter is that of a forcible blow; the machine being intended to operate upon the harder kinds of stone. Messrs. Hunter, of Manchester, have devised a machine for cutting pavement-slabs. Twenty or thirty cutters are fixed to the periphery of a revolving disc ten or twelve feet in diameter. These machines are in use in Dean Forest; some of them will cut 250 square feet of pavement, 1¾ inches thick, in ten hours.

When marble or other stone has been cut into slabs, its further working is effected by machines of various kinds. To reduce it to narrow slips, it is exposed to the action of small circular cutters, ranged parallel on one common axis; the distances between the cutters are made equal to the intended widths of the strips; the marble is slowly brought up to the revolving cutters by the action of pulleys and weights.

Circular pieces are cut from slabs by ingenious machines. Large circles are cut by means of four cutters placed at the ends of the arms of a horizontal cross; the size of the cross determines the diameter of the circle to be cut, and the curvature given to each cutter is made correspondent thereto. When the frame or cross is made to rotate, the four cutters follow one another in the same path, and speedily cut out a circular piece. Smaller circles are cut by means of a hollow cylindrical tool, something like a punch; but it acts by continual rotation, and not by blows. By a modification of this apparatus, round pillars and hollow cylinders or tubes of stone may be cut.

To produce mouldings, or similar symmetrical cuttings in stone, various machines are employed. The turning-lathe is used for circular objects. Iron cutters, with sand and water, are not used here; but the workman acts upon the stone with long, sharp-pointed instruments of steel; and when the shape has been thus roughly produced, it is finished by gouges and other tools. Strips of stone or marble, such as those used for chimney-pieces, have mouldings formed upon their surfaces by different means. The cutters here are in fact grinding tools. They consist of masses of iron, whose surfaces are circular, and have been wrought into various forms, such as hollows, beadings, ogees, &c.; the tool rotates rapidly in contact with the stone, which is brought up close to it by a weight and pulley; and thus a moulding is formed on the surface of the strip of stone, a counterpart of that on the iron tool. A workman applies sand and water to the iron tool. The apparatus is shown in the annexed cut.

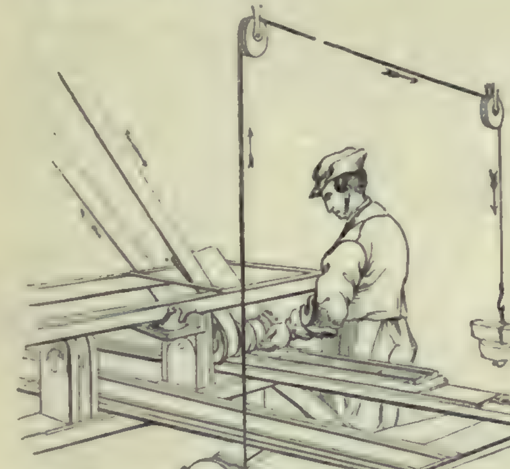

Fig. 2.—Marble Moulding Machine.

The smoothing, grinding, and polishing of marble and stone are effected by machines variously arranged. Large slabs are ground by a plate of cast-iron. The slab, placed horizontally, has a reciprocating motion given to it; the iron plate, resting upon it, has a kind of spiral motion; and the two motions together enable the iron to act equally on all parts of the stone. Sand and water are let down between the two surfaces, through holes in the iron plate. Smaller surfaces of stone or marble are ground by being held down by hand upon the surface of a revolving iron table, kept moistened with sand and water. The Earl of Caithness has recently devised a machine for dressing the surface of Caithness rag slabs, a stone well fitted for street pavements. About 30 iron bars are ranged parallel and vertical, each with jagged teeth at the bottom; a crank movement lifts them all to a certain height, one after another, and lets them fall heavily; the slab slowly moves beneath them, so as to be subjected all over to an equal amount of jagging or chipping. This produces a surface level but not smooth.

The polishing of marble requires tools different from those used in grinding or smoothing. The tools are made of lead or some other heavy substance, and are faced with a peculiar kind of felt, which, when wetted and rubbed to and fro by any convenient machinery polishes the marble. For smoothing and polishing of carved marble, or of small pieces shaped in any irregular way, small pieces of cast-iron, gritstone, smooth stone, slate, &c., are used in various ways.

STOP. [ORGAN.]

STOPPAGE IN TRANSITU is the seizure by the seller of goods sold on credit during the course of their passage (transitus) to the buyer. This principle is said to have been established about 1690 in the Court of Chancery (2 Vern., 203); and it has since been acknowledged in the courts of common law. The transitus is defined to be the passage of the goods to the place agreed upon by the buyer and seller, or the place at which they are to come into the possession of the buyer. This definition does not mean that the term transitus implies continual motion: goods are in transitu while they are at rest, if they are still on the road to the place to which they have been sent. This doctrine of stoppage in transitu entitles a seller, who is empowered to stop the goods before they come into the buyer's possession. The right is not confined to cases of buying and selling. A factor either at home or abroad, if he consigns goods to his principal by the order of the principal and has got the goods in his own name or on his own credit, has the same right of stoppage in transitu as if he were the seller of the goods. Questions of stoppage in transitu sometimes involve difficult points of law. The right of stoppage implies that the goods are in the possession of the seller or factor when he exercises this right. The exercise of the right is excluded in the case of a bill of lading which has been endorsed over; for here the endorsement passes the property in the goods absolutely to the endorsee.

STRABISMUS. [SQUINTING.]

STRAIGHT, STRAIGHT LINE, PLANE. There is no occasion to define a straight line as matter of information; so that we have here only to consider the definitions which have been given and their relative merits, taking them as attempts to produce a mathematical description of straightness.

There are three attempts at definition of a straight line; by Plato (or one of his immediate school), by Archimedes (as is said), and by Euclid. The moderns have repeated these various forms, but have not, to our knowledge, ever succeeded in producing a definition entirely new which did not contain the defects of one or other of the three just mentioned.

The Platonic definition, according to Proclus, is as follows:—"A straight line is that of which the middle parts hide (ἐπιπροσθεῖ) the extremities;" a physical definition, owing its truth to the circumstance of the rays of light proceeding in straight lines, and involving the notion of straightness as a part of its own explanation. This definition has been little if at all used by geometrical writers.

Archimedes defines a straight line as the shortest distance between two points, or at least this definition is often attributed to him, but not correctly. It is one of his postulates in the book on the Sphere and Cylinder, that of all lines drawn between two points the least is that which is straight: but he is too well judging a geometer to assign such a property as a definition. The Arabs substituted the shortest-distance description for the definition in Euclid, and accordingly our earlier editions of Euclid do the same; nor was this flaw removed until 1505, when Zamberti translated Euclid from the Greek. It has often been supposed that this shortest-distance definition is good as a definition, though not proper for a pupil in geometry, an opinion from which we must dissent: for how is it known to those who are yet to learn what a straight line is, whether there can be a shortest distance? That is, how is it known that there are not many distances between two points, on different lines, which are severally shorter than any other distance, and equal to one another? The answer is, no doubt, that the mind has a perfect conception of the impossibility of such a thing; and the rejoinder is—yes, because the mind has a perfect conception of a straight line: that is to say, the definition is only saved from causing confusion by its own uselessness. Again, the supposition that measurement of distances on all manner of curves is to be a preliminary to one of the definitions of a science which treats no curve but the circle, and does not succeed, by reason of certain limitations of process, in measuring distance even on that one, is an incongruity.

Euclid defines a straight line to be that which lies evenly (ἐξ ἴσου κεῖται) between its extreme points. The words ἐξ ἴσου have been translated *ex æquo* by Barocius, *ex æquali* by Zamberti, *equally* by Billingsley (taking some of the oldest translations as specimens). The definition wants precision, but the meaning is obvious. Two points being given, the surrounding space may be viewed in all manner of relations to those two points, as above or below, right or left, &c. The straight line which joins the two points is that which is not more related to one of these notions than to any other; and throughout its whole length takes an even course, without a possibility of being claimed, so to speak, by any one of the surrounding parts of space rather than by any other.

In making such a definition Euclid is well aware that he cannot rest any conclusion upon it, and that in the postulate that two straight lines cannot inclose a space lies all his power of producing a theorem. Why then, it may be asked, does he introduce a definition at all? Why not give the reader to understand that a straight line is a notion universally understood and incapable of definition in simpler terms? To these questions the answer may be twofold. In the first place, he is not answerable for the genius of any language but his own, and it is very possible that to a Greek commencing geometry, εὐθεῖα might be a hard word, and ἐξ ἴσου κεῖται a real explanation; in which case his definition is defensible until it can be shown that he might have chosen a better one. We are not to judge of the force of the last-quoted words from the *ex æquo* of the middle Latin, or the *evenly* or *equally* of the English. Secondly, he is evidently, in some of the first definitions, recalling, and not instilling, notions: he is proceeding with his reader as by words to which both attach a conception, and he tries these words for use by ascertaining that both parties agree on such circumlocution as can be substituted for them.

The greatest defect of Euclid's definition, since it applies even to the view just taken of its intent, is the want of words signifying that ἐξ ἴσου refers equally to *all* adjoining parts of space: Euclid is thinking too much of a plane before he has defined a plane. Suppose, for instance, a sphere, and that lines on a sphere only are contemplated: the line which joins two points ἐξ ἴσου with reference to all adjacent parts of that sphere is not a straight line, but an arc of a great circle.

Is it possible, taking such allowances as Euclid sanctions in the use of figure, to give what shall be, whether difficult or not difficult, capable of use or not capable, a just definition of a straight line? We think it is, as follows:—The Greek geometer implicitly allows (i. 4) a TRANSLATION of figure without change of form or properties: from this, by first defining the plane, a definition of the straight line may be proposed, which we bring forward, not for any value which it has, but because the stipulations of geometry are better understood by consideration of cases proposed for acceptance or rejection, than by any other method.

1. Let two points (A and B) be said to be at the same *distance* from a third (C), when A and C being joined by *any* line, the line CA can be translated, C remaining fixed, so that A shall be brought to coincide with B.

2. A plane is a surface any point of which is equally distant from two given points.

3. A straight line is the intersection of two planes.

In the debates of the normal school, which were taken down in shorthand, and published in 1800, is a discussion on this subject. Lagrange presiding, Fourier, then one of the pupils, proposed the preceding second and third definitions, but without assigning a definition of equi-distance independently of the straight line. He also proposed as the definition of a straight line the locus of a point which is equidistant from three given points; which is faulty, inasmuch as the three given points should not be in one straight line, which cannot be supposed until the straight line is defined. Lagrange admitted the rigor of the definition, but considered that it failed in presenting a sensible image of the thing defined. Another of the pupils however insisted that the idea of distance involved that of a straight line, which is true of distance as a *quantity*, though not necessarily so of equi-distance as a *relation*.

General Thompson proposes to define a straight line as one which being turned about its extreme points suffers no change of place. Lagrange, in the debate above alluded to, suggested the same notion. This definition, we think, offers the most tangible illustration of that of Euclid. Let the two extremities of the intended straight line be situated in a solid; and let them remain fixed in space while the solid takes such motion as, under that condition, it is capable of. The straight line, the line which lies ἐξ ἴσου with regard to the extreme points, then remains fixed. For if any part of it moved, there would be in every position a relation to adjoining parts of space, which would be in a state of continual change. The connexion between this definition by rotation and that of Euclid might require more development to render it as clear as possible: but we think the student's own reflection will lead him to make it satisfactorily. But whatever may be thought of the endeavour to exercise the discrimination of which geometry points out the possibility by framing or arguing on definitions, we do not remember to have seen one so well calculated for the mere beginner as the following:—"A straight line is a straight line."

The postulates relative to a straight line demanded by Euclid (we do not speak of his translators) are: 1. That such a line can be drawn from any one point to any other. 2. That when terminated, it can be lengthened indefinitely. 3. That two such lines cannot inclose (μὴ περιέχειν) a space. It is also tacitly assumed that every part of a straight line is a straight line: that every straight line, infinitely produced, divides a plane in which it lies into two parts, and will be cut by any line drawn from a point on one side of it to a point on the other. It might also have been assumed that two straight lines which coincide in two points, coincide when produced beyond those points; but here Euclid has preferred to assume that all right angles are equal. [RIGHT ANGLE.]

The definition which Euclid gives of a plane, is that of a surface which lies evenly between its bounding straight lines. To this definition there is the serious objection that though a plane may be as easily conceived as a straight line, yet it is actually capable of definition by a straight line. For a plane is the surface any two points of which can be joined by a straight line which lies wholly on the surface. Neither this definition (nor Euclid's) precludes the necessity of a postulate demanding the possibility of drawing a plane through any straight line. Objections might be made to the first part of Euclid's eleventh book, which would require for their answer that another postulate should be granted, similar to that required for a straight line, namely, that if two planes coincide in any portion of surface, they coincide altogether. Euclid does in fact assume a postulate which is not expressly laid down, namely, that a finite straight line can be produced in every plane in which it lies, but we think it may be fairly doubted whether the first three propositions of the book in question are as perfect as they might be made.

STRAIN. [SPRAIN.]

STRAIN AND STRESS. [MATERIALS, STRENGTH OF.]

STRAMONIN. A crystalline body contained in stramonium seeds.

STRAMONIUM, botanically the *Datura Stramonium*, or *Thorn Apple*, an introduced but now frequently self-sown and consequently wild plant, found particularly wherever a garden once has been. The leaves and seeds are officinal. The leaves during drying diffuse a stupifying odour, and become deep grayish green, and then scarcely possess any odour: the taste is disagreeable, saline, and strongly bitter. The seeds are kidney-shaped, flat, about the size of linseed, uneven, nearly black: when bruised the smell is disagreeable and repulsive; taste bitterish and oily; by expression sixteen ounces of fresh seeds yield two ounces of clear fat oil, which has neither taste nor odour. The seeds of the other species of datura are often substituted, perhaps without any great disadvantage. They are also confounded with the seeds of *Nigella Sativa*, which, though black, are smaller, nearly three-cornered, and have an acrid aromatic taste, and in considerable quantity are poisonous like those of stramonium.

The seeds are used to form the extract; they, as well as the unripe capsules, yield the alkaloid called *datura*, which crystallises from its solution in alcohol or water in colourless shining aggregated prisms; without odour when pure, but when impure possessing a strongly narcotic odour; taste at first bitter, then very acrid, and like tobacco. This is extremely poisonous: one-eighth of a grain can kill a sparrow in less than three hours; and the smallest quantity applied to the eye causes very lasting dilatation of the pupil.

Stramonium in small doses causes slight convulsive action about the throat, with dryness of the tongue, disposition to vomit, and general diminution of sensibility, with slight increase of secretion of the skin, mucous membranes, and kidneys; but if the dose be larger, the brain becomes affected, and vertigo, indistinctness of vision, with dilatation of the pupil, disposition to sleep, or coma, but more frequently delirium, are added. The delirium is always peculiar, and the individual manifests a disposition to perform ridiculous actions, or assume absurd positions. If the dose be still larger, and produce fatal effects, the brain is usually found to be much congested, the vessels being gorged with blood. Large bleedings generally save the patient; emetics can rarely be made to act, as is observed when other narcotic poisons have been taken. Stramonium is most useful in cases of increased sensibility, particularly in local affections of the nerves; it is decidedly useful in allaying pain of the sciatic nerve, particularly when combined with ipecacuan. It has been recommended in mania, especially when accompanied with lucid intervals, in epilepsy, and hysteria; but with very variable success, probably to be accounted for by the careless preparation of the medicine. It is popularly used for smoking, to allay paroxysms of asthma, but its employment in this way is quite empirical, and regulated by no clear principle. By the action of heat during smoking, an empyreumatic oil is found, similar in properties to that of hyoscyamus.

STRATEGY (from the Greek *στρατηγία*, which may be translated "generalship") is, properly, the science of combining and employing the means which the different branches of the art of war afford for the purpose of forming projects of operations and of directing great military movements: it was formerly distinguished from the art of making dispositions, and of manœuvring, when in the presence of the enemy; but military writers now, in general, comprehend all these subjects under the terms of grand and elementary tactics. [TACTICS.]

The general principles of strategy and tactics have been and must be the same in all ages. To overcome the enemy, it is necessary to be superior to him at the point of collision, not necessarily numerically, for number only does not always represent the strength or relative strength of an army, but superior when due allowance is made for other advantages or disadvantages. The object then of all strategical combinations should be to bring the mass of the forces in collision with fractions of the enemy; and secondly, to act as much as possible on his communications or lines of operations without exposing one's own. The roads on which an army, or portion of an army, marches, are termed strategical lines, and the belt of ground containing two or more strategical lines, if lying close together, is termed a line of operations. In order then to bring, and always to have the power of bringing, the mass of the forces in collision with fractions of the enemy, it is necessary to choose such lines of operations as are *interior*; interior, that is, with respect to those on which the enemy acts. That is to say, that these lines must be, relatively to those of the enemy, such that the portions of the army moving on them may be more easily or rapidly united than the enemy can be, moving on his, so as to be superior at any particular point to the enemy. As a general rule, then, disregarding the relative rates of marching of armies, cross roads, &c., interior lines are such as are closer together.

Strategy consists, therefore, chiefly in making choice of convenient bases (fortified places or strong positions) in order to place there in security the military establishments of an army; such as the barracks, hospitals, and magazines of ammunition and provisions, previously to commencing offensive operations, or in contemplation of the army being compelled to act on the defensive. In the former case, it may be necessary to decide on undertaking the siege of some fortress on a frontier, should there be none such in possession, for the purpose of holding the neighbouring district in subjection, and commanding the roads by which it may be thought convenient to penetrate into the enemy's country, or by which the provisions and warlike stores may be brought up to the immediate seat of the war. In the latter case, choice is to be made of positions strong by nature, or which may be made so by art, for the army to retire to while disputing the ground gradually, harassing the enemy by frequent skirmishes, or preventing him from receiving supplies by intercepting his convoys on the roads.

Thus, after the battle of Vittoria (1813) the allied British and Spanish armies being at a great distance from the original base of operations in Portugal, and it being intended to carry the war into France, Lord Wellington undertook to besiege St. Sebastian and to blockade Pampeluna, in order, by the possession of those places, to have secure stations for his recruits and magazines while the army advanced into the mountainous districts between St. Jean Pied-de-Port and the sea. On the other hand, the conviction, in 1809, that the British army would be compelled to act entirely on the defensive, induced the English general to take measures for a retreat into Portugal, and to commence, many months before the retreat took place, two chains of strong redouts on the north of Lisbon, in the expectation of being able there to resist effectually the very superior forces of the enemy.

The project formed by Marshal Soult, in 1813, in opposition to that of Lord Wellington, affords also a good illustration of the nature of strategical operations. The French general decided to advance towards Pampeluna in the hope of being able to succour that place, and afterwards to unite his army with that of Suchet in Aragon: he expected also to command the road along the Spanish frontier, by which he might have got to the rear of the allies in a fertile country, where his army could have found subsistence. (Napier, vol. vi.) This project failing, and the battles of the Pyrenees having forced the French army to act on the defensive, Marshal Soult took measures for protracting the war to the utmost.

In the defence of an extensive territory, since it is generally impossible to cover the whole, the principles of strategy indicate that the army should be kept in force on a few of the most important positions. By securing these, the designs of the enemy may be more effectually frustrated than if it were attempted to occupy every post in the country; for the different divisions of the army being in the latter case weak and ill supported, they are liable to be cut off in detail, whereas the difficulty of dislodging a large body of troops from one strongly intrenched position may deter the enemy from attempting it: at the same time the occupation of that position by the defending army may paralyse his movements by rendering it dangerous for him to leave in his rear a force which might prevent him from drawing supplies from his magazines. The evils attending the dissemination of troops over a great extent of country are strongly exemplified in the surprise of the Austrians by Marshal Turenne. The French general caused the several corps of his army to be drawn together towards Befort in such a manner as not to excite notice; and from thence suddenly penetrating into Alsace, in the midst of the enemy's quarters, he defeated the troops before they had time to unite.

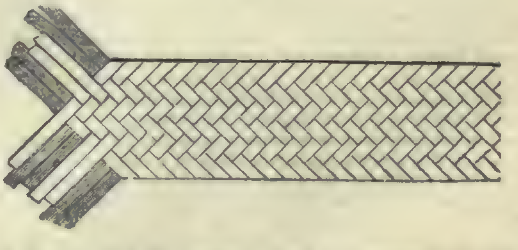
STRAW-PLAIT MANUFACTURE. The domestic character of this branch of industry, which renders it peculiarly important as a means of affording employment to women and children, especially in agricultural districts, may probably account for the circumstance that very little is known of its history. It is not known when the manufacture of hats or bonnets of plaited straw first became important in Italy, where it has long formed one of the leading pursuits of the agricultural population; but it appears from Coryat's 'Crudities,' published in 1611, that "delicate strawen hats" were worn at that time by both men and women in many places in Piedmont. Coryat states that many of these hats had at least a hundred seams, from which it is evident that very fine plait was made at that time. The straw-plait manufacture does not appear to have been followed in England for more than about a century. The wives and daughters of the farmers, before that time, used to plait straw for making their own bonnets, before straw-plaiting became established as a manufacture. Gipsy straw-hats were worn by ladies in this country about 1745-6. When Arthur Young visited Dunstable, in 1768, the straw-plait manufacture appears to have been established, though not very extensively. In Macpherson's 'Annals of Commerce,' published in 1805, Dunstable is described as "a town in the neighbourhood of which the women and children are employed in making hats, baskets, and many fancy articles, of straw, which in their hands assumes a vast variety of figures and colours, and produces considerable emolument, especially since the straw hats have been in general request among the ladies."

The large size of the wheat-straw used in this country for plaiting prevented the home manufacture from entering into competition with that of Italy in articles of fine quality; the straw grown for the purpose in Tuscany being much smaller, as well as superior in colour. This difficulty was in some degree overcome by the expedient adopted in England towards the end of the last century, of splitting the straw, and using the narrow *splints*, or slips of straw, in lieu of whole straws. The operation of splitting is performed by small cutting instruments called *machines*, which have a number of sharp edges so fixed as to divide the straw, by a motion in the direction of its length, into four, five, six, or more equal parts. Before machines were invented, straws were occasionally split with knives by hand; a process which was both tedious and unsatisfactory, since it gave no security for the uniform width of the splints, upon which the beauty of the plait greatly depends. Mr. Corston, in a letter addressed to the Society of Arts in 1810, observes that "by the mere invention of the splitting of a straw a source of employment has been discovered, which has increased the returns in that branch not less than from 300,000*l.* to 400,000*l.* annually."

Greatly as the British straw-plait manufacture had been encouraged by the use of split straw, by improvements in bleaching, and by increased care in the selection of straws of uniform size and colour, it was found, when the re-establishment of peace allowed the free importation of Italian straw hats, that the home manufacture was unable to compete with the foreign, notwithstanding the heavy protective duty levied upon hats or bonnets of straw imported from other countries. The Society of Arts therefore, for a long series of years, offered encouragement to attempts for the improvement of the British straw manufacture, which called forth many interesting communications, and has led to great improvement. As early as 1805, the Society presented a gold medal to Mr. William Corston, of Ludgate Hill, for a substitute, of his invention, for Leghorn plait. His plait was formed of rye-straw. More recently rye-straw has been tried for the same purpose by Messrs. J. & A. Muir, of Greenock, who attempted to establish the straw-plait manufacture in the Orkneys. In plait made of split straw, unless two splints are laid together, with their inside surfaces towards each other, as in the plait called "patent Dunstable," it necessarily happens that the face of the plait exhibits alternately the outer and inner surfaces of the straw, which differ from each other in colour and gloss. Articles made of split straw are also inferior to those of whole straw of equal fineness, in pliability and durability. Another circumstance which greatly increases the beauty of Leghorn plait is the mode of joining it, so as to form, by the combination of several narrow strips, an extended sheet of plaited work. British split plait is usually joined by making the several rows of plait overwrap each other a little, and then stitching through the two overwrapping pieces with a needle and thread. The surface of a hat or bonnet formed in this manner consists of a series of ridges; and part of each row of plait is concealed by that next above it, so that to form a band one inch wide, with a plait a quarter of an inch wide, it will be necessary to use *five* pieces of plait; at least a fourth part of the width of each being absorbed by the overwrapping joint. Leghorn plait is formed in such a manner that it may be joined without this loss; the edge of one row of plait being, as it were, knitted into the edge of the other, in such a way that the pattern may appear uninterrupted, and the line of junction be almost invisible.

The home manufacture of Italian straw was introduced by Mr. Parry in 1822. The ears are cut off with a knife, and the straws are then carefully sorted to obtain uniformity in length, thickness, and colour. The plait, of which an engraving is given below, consists of thirteen straws. These are tied together at one end, and then divided into two portions; six straws being turned towards the left side, and seven to the right, so that the two portions of straw may form a right angle. The seventh or outermost straw on the right-hand side is then turned down by the finger and thumb of the right hand, and brought under two straws, over two, and under two. This being done, there will be seven straws on the left and six on the right side of the angle; and the next operation is to turn down the outermost of the seven with the left-hand finger and thumb, and to pass it under two straws, over two, and under two. The right side will again have seven, and the left side six straws; and the plaiting must be continued in the same manner, alternately doubling and plaiting the outermost seventh straw

Fig. 1.



from side to side, until it becomes too short to cross over so as to double on the other side of the angle. The plaiter then takes another straw, and puts it under the short end at the point of the angle (the middle of the plait), and, by another straw coming under and over the joined one from both sides of the angle in the operation of plaiting, it will become fastened; the short end being then left out underneath the plait, and the newly fastened straw taking its place on that side of the angle to which the short one was directed. The plait thus formed is represented in the cut *fig.* 1, about double the real size. The plait is formed in pieces of great length, which are adjusted in spiral coils, with their adjacent edges knitted together, so as to form the large circular pieces of plait which, under the name of hats, or *flats*, are so extensively exported from the north of Italy. The mode of effecting the junction may be explained by the help of the annexed cuts. *Fig.* 2 represents, about four times the real size, the two adjacent edges when knitted together; the dotted lines indicating the edges of each piece of plait, and showing how far the angular folds, or *eyes*, of one piece are inserted into those of the adjoining piece. The thread by which the two rows of plait are held together is here straight, and is entirely concealed in the plait. The joint is, indeed, only to be detected on either side by the slightly increased thickness of the plait where the angles are inserted into each other, and the thickness of the thread itself. The mode of junction may perhaps be better understood from *fig.* 3, which represents the pieces of plait drawn a little asunder, and shows the course of the thread, which is indicated by dotted lines where it is covered by the straw. The operation is performed by pushing a needle through the folds in the required order, and, after passing it through as many as can be conveniently done at once, drawing it through in the manner of a bodkin, leaving its place to be taken by the thread. Sometimes, for the sake of expedition, only every alternate fold is threaded. In arranging the plait in a spiral coil, as in making a hat, it is necessary, in a few places, to force two loops of the smaller circle into one of the larger circle adjoining it, to allow for their different diameters.

Fig. 2.

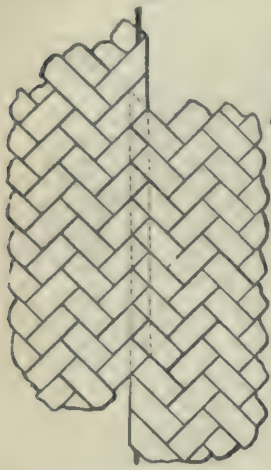


Fig. 3.

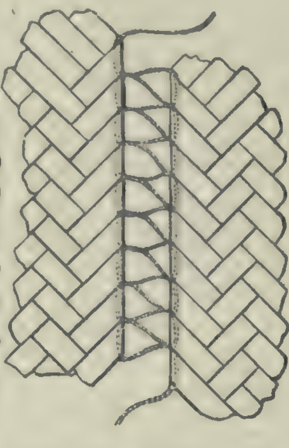


Specimens have been produced in England even finer than real Leghorn; but such extreme fineness can only be attained by a sacrifice of strength, and an increase of work.

The material commonly used for plait in Tuscany is the straw of *Triticum turgidum*, a variety of bearded wheat, which seems to differ in no respect from the spring wheat grown in the vale of Evesham and in other parts of England. It is grown in Tuscany solely for the straw, and not for the grain; and the upper joint of the straw is that chiefly used for plaiting. The straw is pulled while the ear is in a soft milky state; the corn having been sown very close, and consequently produced in a thin, short, and dwindled condition. It is then dried by spreading it thinly upon the ground in fine hot weather, and afterwards tied up in bundles and stacked, for the purpose of enabling the heat of the mow to drive off any remaining moisture. After remaining in the mow for about a month, it is spread out in a meadow and exposed to the action of dew, sun, and air, in order to bleach it. The straw is frequently turned during this operation; and after it is completed, the lower joint of the straw is pulled off, leaving the upper joint, with the ear attached to it, for use. This part is then subjected to the action of steam, and to fumigation with sulphur, in order to complete the bleaching, after which it is ready for use. It is tied up in bundles, and imported to England in this state.

Bleaching with sulphur is commonly practised in this country. The apparatus for this process usually consists of a cask open at both ends, with its seams papered. It is set upright on the ground, having a hoop nailed to it inside, about 6 inches beneath the top, to support another hoop with a net stretched across it, upon which the straw is laid loosely. The cask is then covered with a tight overlapping lid, stuffed with lists of cloth. A brazier of burning charcoal is inserted beneath the cask, and upon this is placed an iron dish containing pieces of brimstone. The brimstone soon takes fire, and the sulphurous acid gas evolved during its combustion fills the cask, and bleaches the straw in three or four hours. After bleaching, the straw is aired and softened by spreading it upon grass for a night, and it is then ready for splitting. Chloride of lime is also employed as a bleacher.

Straw may be dyed, for ornamental purposes, of many different colours. Blue is given by a boiling hot solution of indigo in sulphuric acid; yellow, by decoction of turmeric; red, by boiling hanks of coarse scarlet wool in a bath of weak alum-water containing the straw; or directly, by cochineal, salt of tin, and tartar. Brazil wood and orchil are also employed for dyeing straw.

The *splints*, or pieces of split straw, being curved in a way which would impede the operation of plaiting, require to be flattened between rollers. These, as well as the whole straws used in other kinds of plait, are moistened with water to render them easy to work. It need hardly be observed that cleanliness is indispensable to the beauty of the plait. Hence the Italian plaiters find the spring to be the most favourable season for the work, as the plait is not then exposed to the smoky atmosphere of the huts as in winter, nor to the dust and perspiration of summer. The Italian plait is dressed and polished by passing it forcibly between the hand and a sharp piece of wood.

The British straw-plait district comprises Bedfordshire, Hertfordshire, and Buckinghamshire; those counties being the most favourable for the production of the wheat-straw commonly used for English plait. The manufacture is also followed in a few places in Essex and Suffolk; but very little in other counties. The principal markets are Luton, Dunstable, and St. Alban's. In Italy the manufacture is chiefly followed in the neighbourhood of Florence, Pisa, Siena, and the Val d'Arno, in Tuscany; and it is also established in Venice and other places. There, as in England, the manufacture is purely domestic. The chief market is Florence; and the demand is principally from England, France, Germany, and America.

There are many kinds of straw-plait made in England, known by the names of *whole Dunstable, patent Dunstable, split straw, Devonshire, Luton, Bedford, Leghorn, Italian, backbone, lustre, wave, diamond, &c.*,—differing one from another in the straws being whole or split, in the thickness of the straws, in their number, or in other particulars. There has also, within the last few years, been a great extension given to the trade, by the combination of lace, whalebone, mohair, and other substances with the straw, leading to the production of very beautiful fabrics.

In the 'Companion to the Almanac' for 1861, is an article by Mr. Charles Knight, describing many of the features in the English straw-plait manufacture of the present day. A few of the chief facts will here be given in a condensed form. The census of 1851 showed that 28,000 females of all ages were engaged in Great Britain in this manufacture; of whom 10,000 were in Bedfordshire, 9000 in Hertfordshire, 3000 in Buckinghamshire, and the rest scattered in other counties. When seasons are favourable, and fashion tends to the wearing of straw hats and bonnets, many girls and women turn their attention to this trade, who would otherwise seek engagements as domestic servants. Such was the case in 1859, when Luton, Dunstable, and St. Alban's were very busy with the straw-plait trade. During that season, one single firm, Messrs. Vyse, purchased as much plait as 3000 persons could prepare, and made up 9000 straw hats and bonnets weekly. Men are engaged in cutting and sorting the straw, drying and brushing the plait, and stiffening and blocking the hats and bonnets when made; the other processes are undertaken by females. Taking all the branches, it was estimated in 1851 that 70,000 persons were thus employed in Great Britain, and that the yearly returns were 900,000*l.*; it is supposed that in 1859 these numbers were doubled. The manufacture of Brazilian grass hats is one of the peculiarities of the St. Alban's district. In the country places surrounding the three chief towns for the manufacture, straw-dealers buy straw from the farmers, sort and cut it, bleach it, and make it up into bundles. Weekly markets are held in the towns, at which the plaiters buy the straw. The women and girls make up the straw into plaits of various kinds and widths, which are either sold at once to itinerant dealers or middlemen, or are taken to market. The bundles of plait are bought by hat and bonnet makers, who either work at their own houses, or are employed in large establishments by the chief firms. These straw and straw-plait markets are held in the open streets of the three towns. No plaiters are employed by the manufacturers; the straw is bought already plaited, and ready to be made up into hats and bonnets. Much taste and skill are shown in the making of the better kinds of straw bonnets, and the weaver occasionally earns high pay. The manufacturers attend to all the fluctuations of fashion; and the workpeople have to adapt themselves to frequent changes in form, material, and manipulation.

A small import duty, formerly imposed on foreign straw-plait, was repealed in 1860.

STRAWBERRY. The botanical characters of the strawberry have been given in the NAT. HIST. DIV. Of the cultivated strawberry, the varieties are almost endless, and nearly every season something new is produced. In the Fruit Catalogue of the London Horticultural

Society, upwards of sixty varieties are named as worth cultivating, and there are as many, or perhaps more, which are reckoned worthless.

Strawberries may be propagated either by means of their suckers or runners, or by sowing seed. The young plants will generally bear the year after they have been planted or sown. In order to obtain the fruit in perfection, they should be planted where they have access to abundance of light and air. Plants grown from runners are best for new beds, and should be planted out in March, in beds with three or four rows, leaving an alley between each bed. The alleys should be wide, the beds kept clear from weeds, and the runners cut at least three times in the season. In the autumn the rows should be dug between, and in the spring some straw or dung should be laid between the rows. If the manure produces too luxuriant a growth of the plants, it should not be employed. The rows of the beds should be two feet apart, the plants eighteen inches asunder, and the alleys three feet wide between each bed. The duration of the plants is about three years. As they are diœcious, care should be taken that there are male plants in the bed in the proportion of about one to ten. The *wood-strawberry* is best produced from seed, which should be sown as soon as it is obtained from the fruit, and should be planted in beds in March, in the same way as the others. The *alpine strawberry* is best grown from seeds, which should not be sown till the spring, and may be planted in July or August, in rows at the back of hedges or walls, in a rich or moist soil. The duration of these and of the last seldom exceeds two years.

Strawberries, when ripe, may be eaten in almost any quantity without injury. They are frequently eaten mixed with sugar and cream, or wine. When ripe and well grown, they hardly require such additions; but when their sugar is deficient, this ingredient may be safely added; and the addition of wine under these circumstances should be preferred to cream, as the latter is very liable to disagree with disordered stomachs.

STRENGTH OF BEAMS, PILLARS, &c. [MATERIALS, STRENGTH OF.]

STRING-COURSE, a projecting *course* of masonry forming a *string* or horizontal line on the face of a wall, and consisting of a series of mouldings, as in Gothic, or of a flat surface (either plain or enriched), as in Italian architecture. In both styles, string-courses admit of great variety, and contribute very much to decoration, while they are in themselves essential members, inasmuch as they serve to define the internal division of the building, corresponding with the floors of the several stories; and by separating one tier of windows from another, to mark each as a distinct portion of the general composition, complete as regards itself, though secondary to the other. While they separate, they serve also to connect and combine the successive stages of a building; and to produce a due admixture of horizontal with perpendicular lines.

STRONTIA. [STRONTIUM.]

STRO'NTIUM (Sr). A peculiar metal found in combination with oxygen and carbonic or sulphuric acid, and forming the carbonate and sulphate of strontia. From the very considerable resemblance existing between baryta and strontia they were once supposed to be identical. Crawford and Sulze noticed a difference between them, and in the year 1792 Dr. Hope established sufficient differences to prove that they were completely distinct bodies, and the newly discovered body was named *Strontia* or *Strontites*, from Strontian in Scotland, the place in which it was discovered.

Strontium was procured from the carbonate of strontia by Davy in 1808; the method adopted is that which we have described for obtaining barium [BARIUM] from the carbonate of baryta. It is a malleable metal of a pale yellow colour, is heavier than sulphuric acid, fixed, difficultly fusible, and not volatile. When exposed to the air it attracts oxygen, and becomes converted into strontia; when thrown into water, it decomposes it with great violence, producing hydrogen gas, and forming with the water a solution of strontia.

Oxygen and Strontium, as just mentioned, readily unite, constituting the *protoxide, or strontia* (SrO), which in combination with acids exists largely in nature, and the *peroxide*, which is entirely an artificial product. The simplest mode of procuring the protoxide, or strontia, when required to be free from water, is to dissolve the native carbonate in nitric acid, and to decompose the crystallised nitrate obtained at a red heat; or the sulphate of strontia, which is a much more common substance, may be converted by the well known means first into sulphide and then into nitrate. The properties of strontia are, that it has a grayish-white colour; its specific gravity is between 3 and 4; it is very infusible, not volatile, has an acrid taste, and has an alkaline reaction on vegetable colours. On comparing these properties with those of baryta, it will be observed that there is considerable resemblance between them, but they differ in one remarkable respect, namely, that strontia, unlike baryta, is not poisonous. When exposed to the air it attracts carbonic acid, and is reconverted to the state of carbonate.

Strontia and Water combine to form at least two compounds: when a small quantity of water is poured upon strontia, it slakes, gives out heat, is rendered white, and becoming a hydrate, it is fusible at a white heat, but does not part with its water. Its formula is $SrOHO$.

According to Davy, strontia is soluble in about two hundred times its weight of water at common temperatures. The solution is called *Strontia Water*, and is occasionally employed as a chemical reagent; it acts energetically as an alkali on vegetable colours and in saturating acids. In boiling water strontia is much more soluble than in cold. As the solution cools, crystals, the primary form of which is a square prism, are deposited, and these appear to consist of $SrO, 9HO$.

Peroxide of Strontium (SrO_2) may probably be obtained, as the peroxide of barium is, by passing oxygen gas over strontia at a red heat, or by heating it with chlorate of potash.

Neither nitrogen nor hydrogen unites with strontium.

Chlorine and Strontium combine to form only one compound, consisting of ($SrCl$).

The best mode of procuring this salt is to dissolve carbonate of strontia in dilute hydrochloric acid, and to evaporate the solution to its crystallising point, the chloride containing water then separates in long slender crystals, which consist of one equivalent of chloride and one equivalent of water. When exposed to heat the water is expelled, and a solid white chloride remains. The crystals deliquesce in a moist atmosphere, are soluble in twice their weight of water at 60°, and still more so in boiling water; this salt is soluble also in alcohol, and the solution when burning exhibits the peculiar red flame characteristic of the compounds of this metal.

Chloride of strontium may be more directly, but less eligibly, prepared than in the mode now described, by passing chlorine gas over heated strontia; oxygen gas is expelled, and chloride of strontium remains.

Fluoride of Strontium (SrF) is an insoluble pulverulent compound.

Sulphide of Strontium (SrS) may be formed either by heating the native sulphate with charcoal, or by fusing strontia and sulphur in a green glass tube. It dissolves in hot water, and as the solution cools crystals of sulphide of strontium are formed. They appear to contain water.

This compound is used for the preparation of the salts of strontia, the sulphate being a much more common substance than the carbonate, which is preferable however when obtainable.

We shall now describe three oxisalts of strontia, two of which exist in nature, and the third is occasionally employed in chemical researches.

Carbonate of Strontia; Strontianite.—This was the first discovered compound of strontia; it occurs crystallised and massive. Primary form, a right rhombic prism. Cleavage, parallel to the lateral faces of the primary form. Fracture, uneven. Hardness, scratches carbonate of lime, but is scratched by fluor-spar. Colour, white, greenish, grayish, and brown. Streak, white. Lustre, vitreous. Transparent, translucent. Specific gravity 3·605.

Before the blow-pipe it fuses, and gives a purple light. It dissolves with effervescence in dilute nitric acid, and the solution is precipitated by sulphuric acid.

Massive Varieties.—Amorphous, globular. Structure fibrous, sometimes granular.

Found at Strontian in Scotland, Braunsdorf in Saxony, and in Peru.

Analysis by Klaproth :—

Carbonic acid	30·
Strontia	69·5
Water	0·5
	100·

Stromnite, or *Barystrontianite*, or *Barytiferous Carbonate of Strontia*, is a mineral found at Stromness in Orkney. It occurs massive. Structure fibrous. Hardness 3·5. Specific gravity 3·7. Lustre somewhat pearly. Translucent on the edges. Colour grayish and yellowish white. It is soft and brittle. Effervesces with acids, but does not melt before the blow-pipe.

According to Dr. Traill, who discovered this substance, it consists of—

Carbonate of strontia	68·6
Sulphate of baryta	27·5
Carbonate of lime	2·6
Oxide of iron	0·1
Loss	1·2
	100·

Carbonate of Strontia ($SrOCO_2$) may be artificially obtained by several processes; as by exposing strontia water to the air, or by adding an alkaline carbonate to it; or by decomposing any soluble salt of strontia, by means of an alkaline carbonate, &c. In whatever mode obtained, it is a colourless insipid powder, quite insoluble in water, decomposed by acids with effervescence, and by exposure to a high temperature. It is used for preparing the various salts of strontia.

Sulphate of Strontia; Celestin.—Exists largely in nature. It occurs crystallised and massive. Primary form a right rhombic prism. Cleavage easy, parallel to the base of the primary form, but less so in the direction of the lateral faces. Fracture conchoidal, uneven. Scratches carbonate of lime, but it is scratched by fluor-spar. It is brittle. Colour white, bluish, reddish-white. Transparent; translucent. Lustre vitreous. Specific gravity 3·858.

The *Massive Varieties* are nodular, tabular, and amorphous. Structure columnar, fibrous, granular.

It is not acted upon by acids. Before the blow-pipe it decrepitates and fuses into a white friable enamel. The powder becomes phosphorescent on a hot iron.

According to Klaproth it consists of—

Sulphuric acid	42
Strontia	58
	100

This substance occurs near Bristol, in Sicily, at Bex in Switzerland, &c.

Sulphate of Strontia and Baryta; Grunerite.—This mineral is found in Hanover. It occurs massive. Its structure is radiated. Hardness 3·0 to 3·5. Colour white, with sometimes a shade of blue. Translucent. Lustre vitreous. Specific gravity 3·76.

Sulphate of Strontia ($SrOSO_3$) may be obtained artificially, by adding sulphuric acid, or a sulphate, to any soluble salt of strontia. It is a colourless, insipid, heavy powder, insoluble in water, and dissolved only by strong sulphuric acid, from which it is precipitated by water.

Nitrate of Strontia ($SrONO_5$) is procured by dissolving the carbonate in dilute nitric acid, or by decomposing the sulphide of strontium with that acid. The solution is colourless, and by evaporation it crystallises in octohedrons, which are soluble in five parts of water at 60°, and in half a part at 212°. It is insoluble in alcohol, but when finely powdered and mixed with it, the alcohol burns with a beautiful red flame.

Under peculiar circumstances a hydrated nitrate of strontia is formed, containing four equivalents of water. The form of this is an oblique rhombic prism.

The salts of strontia are occasionally used in chemical investigations, and in giving a crimson flame to fire-works.

STROPHE (στροφή) is a set of verses composed according to a certain system of metres. The word is derived from στρέφω, "to turn," as in the lyric, especially the choral poetry of the Greeks, this part of a poem was sung during the movements and dances of the chorus. In modern times such a combination of verses, written either in the same or in different metres, is commonly designated by the Italian name stanza. The division of a poem into strophes was however applied by the ancients only to lyric poetry, and here one strophe seldom exceeded the number of four verses, with the exception of the dramatic and other choruses, in which a strophe sometimes contains a considerable number of verses. However different the metre of the several verses may be, there is always a unity of rhythm in them which characterises a strophe as an artistic whole. The various kinds of strophes were designated by the ancients by various names which either indicated the number of verses they contained, such as disticha, tristicha, tetrasticha, &c., or were derived from the name of their inventors, or from the characteristic metre in which they were composed, such as the Alcaic, Sapphic, Choriambic strophe, &c. Again, strophes in which all the verses are of the same metre are called monocola; and those consisting of verses of two, three, or four different metres, are called dicola, tricola, or tetracola. The choral poems of the Greeks generally consisted of three main parts, strophe, antistrophe, and epode. The antistrophe always corresponds in its metre with the strophe, and thus forms a second stanza, equal to the first; the epode differs from both, and forms the concluding stanza of a chorus. (G. Hermann, 'Elementa Doctr. Metr.')

STRO'PHULUS is an eruption of pimples upon the skin, which frequently occurs in infants whose health is disordered by the irritation of teething or any other cause. Dr. Willan describes the following forms of the disease:—

1. *S. intertinctus*, of which the vulgar name is Red-gum or Red-gown. The eruption in this form consists of vivid-red distinct papulæ, scattered in varying numbers over the cheeks, the arms, the backs of the hands, or, in some cases, the whole body. After an uncertain duration the papulæ disappear, the cuticle separating in scurf; but very frequently the fading of one eruption is rapidly followed by the appearance of another, which passes through similar stages, and generally spreads further over the skin. A few of the papulæ in each eruption sometimes assume the character of small pustules, a little fluid being formed in their apices: but this commonly disappears without bursting. The origin of the eruption may usually be traced to disorder of the digestive organs, by a gentle correction of which it may be cured. A sudden repulsion of it by exposure to the cold, or any injudicious remedies, may bring on diarrhœa, and even severe general illness. In itself it is a disease of no importance.

2. *S. albidus* differs from the preceding only in the colour of the papulæ, which consist of minute whitish specks, slightly elevated, and usually surrounded by a pale ring of red. They appear in the same situations as those of the first variety, are referrible to a similar origin, and require no other treatment.

3. *S. confertus* is often called the Tooth-rash, and the Rank Red-gum. It occurs only during the process of teething, and consists (in children of three or four months old) of small closely-set papulæ, less vivid but more permanent than those in *S. intertinctus*. Their usual seat is on the cheeks and sides of the nose; sometimes they extend to the forehead and the arms, and sometimes large papulæ appear upon the loins. If the eruption occurs when the infant is eight or nine months old, it generally assumes a severer form: one or two extensive patches appear on the arms, shoulder, or neck, the papulæ in each being hard, large, and set so closely, that the whole surface of the skin seems bright red. These usually continue for a fortnight, spreading slowly from one part to another, and then fade, leaving the part, after the exfoliation of the cuticle, rough and discoloured for a week or two longer. A similar, but more obstinate and painful form of eruption, sometimes appears on the lower extremities and the lower part of the trunk. It is never advisable however to adopt any active treatment for the remedy of this variety of the disease. It commonly continues during the whole of the early period of dentition; but it affords in some measure a safeguard against more serious disorders, and disappears soon after the first teeth have cut through the gums.

4. *S. volaticus* is characterised by small circular clusters of from six to twelve bright-red papulæ, which break out successively in many different parts of the body, remaining in each for about four days, and then becoming brown and disappearing with scurf. The complaint generally lasts three or four weeks, and passes in successive eruptions over a considerable part of the body. It is attended by slight fever and general disturbance of the system, and is most common in children of from three to six months old.

5. *S. candidus* is distinguished by the papulæ being larger than in any other variety. Their surfaces are smooth and shining, and, their bases not being inflamed, they seem paler than the adjoining skin: they usually last for about a week, and disappear in the same manner as those in the preceding forms. An eruption of this kind is most common in children a year old, who have shortly before its appearance suffered from some acute disease. It requires no active treatment: like all the other varieties of the disorder, it ceases with the irritation from which it has its origin.

STRUMA. [SCROFULA.]

STRYCHNIC ACID. [NUX VOMICA, ALKALOIDS OF.]

STRYCHNINE. [NUX VOMICA, ALKALOIDS OF.]

STRYCHNOS NUX-VO'MICA, *Medical Properties of.* The genus Strychnos, consisting of about twelve species, is remarkable for containing among these some which possess only mild or beneficent properties, while others are endowed with more potent and destructive powers than almost any other members of the vegetable kingdom. This extraordinary difference is presumed to be owing to certain species containing only an extractive, which is tonic and febrifuge, while others contain one, two, or three alkaloids, which are extremely poisonous. This is true as far as the *S. Nux-vomica*, *S. Ignatia*, *S. Colubrina*, and *S. Tieuté* are concerned, all of which contain either *Strychnia* or *Brucia*, and some both of these alkaloids; *S. Sancti Ignatii* contains an alkaloid called Igasurine [NUX-VOMICA, ALKALOIDS OF]; but it does not apply to the *S. toxifera* (Schomburgk), in which no alkaloid has been detected. It must be admitted, however, that the *S. toxifera*, though equally fatal with the others, produces death in a different way. Those possessed of an alkaloid destroy life by exciting tetanic spasms, while the *wourali*, or *worary*, or *urari* (prepared from the *S. toxifera*), produces diametrically opposite effects, as the muscles of voluntary motion are paralysed by it. The only species strictly officinal is the nux-vomica, poison-nut, or ratsbane, of which the seeds are employed, and to this our attention will be at present confined.

Strychnos Nux-vomica is a native of Coromandel, Malabar, Ceylon, and other parts of India, growing in sandy places, and attaining the size of a tree, but short, crooked, and sometimes twelve feet in circumference, flowering in the rainy season. The fruit is about the size of a St. Michael's orange, with a bitter astringent pulp, and containing from three to five seeds. The pulp may be eaten, but the seeds are poisonous and officinal; each seed is flattish or very slightly concave on the side of the umbilicus, convex on the other, thickened at the margin, peltate, about three lines in thickness, and clothed with dense grayish, silky, or velvety hairs, which towards the umbilicus are arranged in concentric circles. The testa or coat is thin, the nucleus white or grayish, hard, horny, or cartilaginous, bipartite or divided by a cavity in the centre; the embryo is near the margin of the seed, and its position is often indicated by a prominent point.

Owing to the hard cartilaginous nature of the seeds, they are extremely difficult to reduce to powder or to slice. Different expedients are adopted to accomplish this. The entire seed is devoid of odour, but the powder has a peculiar one, somewhat resembling liquorice; the taste is nauseously bitter. *Nux-vomica* should never be purchased in the state of powder, as it is frequently adulterated with common salt or even emery-powder.

An oil is expressed from the fresh seeds, which is used for burning.

Nux-vomica seems to exert a deleterious influence alike over vegetables and animals; there is, however, a difference of susceptibility to its action in different classes of animals, since a much larger quantity is necessary to destroy herbivorous than carnivorous animals.

The degree of effect varies with the quantity employed, but it seems to be the same in kind, being confined to the ganglionic system of nerves and the spinal cord, extending as high up as the *medulla oblongata*, and, according to Flourens, influencing even the *cerebellum*, but certainly not directly affecting the *cerebrum*. Hence in fatal cases the intellect is not disturbed till the extinction of life. The decapitation of animals does not hinder the characteristic action of *nux-vomica*, while, on the other hand, the removal of the spinal-marrow completely prevents its peculiar agency, even though artificial respiration be maintained. "From some experiments of Segalas, it appears also to exhaust the irritability of the heart; for in animals he found that organ could not be stimulated to contract after death, and life could not be prolonged by artificial breathing. *Nux-vomica* differs from all narcotic poisons, by not exhausting the sensibility. During the intervals of the fits the sensibility is on the contrary heightened, and the faculties acute." (Christison.)

Three distinct degrees of action may bè observed from the use of *nux-vomica*. In small doses the ganglionic system appears chiefly to be affected, and this so slightly, that any phenomena are observed only in cases of disease, particularly in hysterical and weak persons. The secretions are increased, both of the intestinal canal, the liver, the kidneys, and of the skin, accompanied with an increase of appetite and improved digestion. Hence, in small doses it is a useful adjunct to aperient and diuretic medicines.

It is in the second degree of action that the characteristic effects of *nux-vomica* begin to appear. The patient experiences a feeling of weight and weakness in the movements of the limbs, inducing him to remain at rest; while his mind is restless, sad, depressed, and anxious for solitude and darkness, as he is peculiarly sensitive to light, noise, or the movement of the surrounding objects. With an augmentation of the dose, these phenomena are increased, and the contact of any external body causes a feeling like an electric shock, the voluntary muscles are no longer under the control of the will, and the individual staggers on the least attempt at walking. At the beginning of these occurrences the pulse is hard and quickened; the gums, cheeks, and eyes reddened, and the respiration more frequent; but when the nervous system is more affected, the hardness of the pulse subsides, the countenance becomes of an ashy paleness, the eyes appear sunken, articulation is difficult and indistinct, breathing is laborious, and accompanied with violent spasms of the larynx, and the other muscles of respiration are irregular in their action. After these symptoms have lasted six or twelve hours, they subside, and a great increase of the secretions is observed to follow; itching of the skin, with much perspiration, even accompanied with an eruption of vesicles or large blebs; the secretions of the serous membranes, of the kidneys, and of the mucous membranes, are sensibly increased, those of the latter sometimes becoming bloody. During this period the patient complains of heat in the stomach and throat, of thirst, of foul taste, and rancid eructations, with nausea, and occasionally even vomiting. While the augmented secretions are taking place, the more prominent nervous symptoms disappear; and in a few days the sufferer recovers entirely from the debility and excessive sensibility.

The third degree of action manifests itself by tetanus and asphyxia, occurring in single paroxysms, alternating with paralytic torpor. The paroxysms become longer, and the remissions shorter, in which however, till death close the scene, the intellect remains unaffected. While the voluntary muscles are entirely withdrawn from the control of the will, the pulse sinks and becomes slower, the breathing more and more laborious ("the external muscles of the chest may be felt during the fits as hard almost as bone; and, according to an experiment of Wepfer, the diaphragm partakes of the spasm of the external muscles:" Christison). The belly swells and exhibits blue marks, the countenance is livid, and in a paroxysm of tetanic rigidity the breathing ceases, though the heart's action and the peristaltic motion of the intestines continue for some time; and, if an artery be opened, black carbonaceous blood issues. "Death, however, does not always take place by tetanus: in some cases the departure of the convulsions has been followed by a fatal state of general and indescribable exhaustion." (Christison.) Thus, after the spasms have lasted twelve, sixteen, or twenty-four hours, and completely disappeared, the individual has nevertheless died, after being apparently in a state of safety. This has been ascribed to the depressing effect on the heart's action, through the medium of the nervous system, of long-continued pain. Or the individual may suffer an attack, after the primary symptoms have subsided, of inflammation of the stomach and intestines, which may or may not prove fatal.

Vomiting does not always occur, though the name would seem to imply the frequency of this symptom.

Nux-vomica is important not only for its formidable properties, but for the illustrations it furnishes to certain physiological doctrines. Thus, when used in cases where a portion only of the body is paralysed, it excites convulsions in the paralysed part before any action be observed in the sound parts. "The paralysed parts are the seat of tetanic shocks, of a prickly sensation, and of a perspiration, which is not observed elsewhere. In hemiplegia the sound side of the body remains tranquil, while the affected one is the seat of extreme agitation; the tetanic attacks succeed each other rapidly, and an abundant exudation takes place. Even an anomalous eruption has been observed, while the healthy side has been perfectly free. One side of the tongue is sometimes sensible of a decidedly bitter taste, which is not perceptible on the other. If the dose be augmented, both sides become the seat of tetanic action, though not equally so." (Magendie.) It is also very remarkable that the contact of any external body with any part of the frame of an individual under the influence of *nux-vomica* which is supplied with nerves originating from the spinal cord, immediately excites convulsive actions. In persons poisoned by *nux-vomica*, whether the seeds or bark (false Angustura bark), the mere act of touching the skin to feel the pulse has excited again the convulsive motions. Of these two phenomena, namely, the action of strychnia on the paralysed limbs previous to causing any obvious effect on the sound organs, and of the contact of an extraneous body exciting the tetanic throes, the following explanation has been given by Mr. Grainger:—"Strychnia acts by preference on the paralytic limb or limbs, because the cerebral control is removed from the paralysed limb. If the cord be divided, the pure spinal power remaining, when the skin is touched the limb is retracted, and must be retracted, because the cerebral control is wanting. So when the spinal cord is stimulated by strychnia, it must act on the limb or limbs from which the cerebral power is withdrawn."

Nux-vomica acts most rapidly when introduced into a vein, and in other instances in the ratio of the absorbing power of the part; but it produces no effect when applied directly to a nerve or to the brain.

In fatal cases the morbid appearances vary according to the period at which death occurs. When death results from asphyxia, the brain is gorged with blood, and the texture softer than natural. When death takes place at a late period, sometimes appearances of inflammation are found in the stomach and intestines; but frequently these are absent. A tetanic stiffness remains in the corpse till decay commences: this state of rigidity, however, does not invariably occur.

The powerful properties of *nux-vomica*, and the rapidity of its action when administered in the state of a pure alkaloid, strychnia, or its salts, have deterred medical men from making so extensive a use of it as its therapeutic qualities entitle it to. The necessity for care in its administration is manifest from the facts, that death resulted in one instance merely from a woman grating cheese with a file which had been previously used to rasp seeds of *nux-vomica*; and in another instance death ensued from three grains of the alcoholic extract being taken at once. The consequence of a salutary dread of it being entertained has been that it is generally employed only as a last resource, instead of being used at an earlier period. It might, however, be beneficially used, with due caution and careful superintendence, in many cases of hysteria and hypochondriasis, dependent on irregular action of the nerves of the ganglionic system. In cases of hysterical paralysis, accompanied with greatly impaired sensibility, it would be more influential than any other agent in a disease at once tedious and distressing.

In paralysis it has been found more uniformly beneficial than most other remedies, though success has not always attended its employment. It is certainly better suited for some forms of paralysis than for others.

It is most serviceable in cases of paralysis of parts which derive their nerves from the ganglionic system or spinal cord. Hence it is more serviceable in *paraplegia* than in *hemiplegia*, in palsy of the bladder, of the rectum, and even in some cases of chronic diarrhœa dependent on atony of the intestines. It is more serviceable in the palsies which follow fevers, rheumatisms, repelled eruptions, habitual drunkenness, and exposure to noxious metals, such as lead or mercury, and merely depressed nervous power, than in those which result from effusion of blood. Its use is altogether improper immediately after an apoplectic seizure, and indeed whenever vascular fulness or organic disease of the brain is supposed to exist. Though less useful in affections of the nerves which arise from the brain, it has nevertheless proved beneficial in some cases of amaurosis, in which the endermic method of application has been employed, rather than the internal administration of it. Deafness has also been cured by it. When employed in paralysis of any of the limbs, an auspicious sign of its beneficial influence is a feeling of formication, and often of sweating, with or without an eruption, and spasmodic twitchings in the limb, while the rest of the body is unaffected.

It was conjectured by Batka, and it has since been proved by Dr. O'Shaughnessy, that the false Angustura bark [GALIPEA] was the bark of the *Strychnos nux-vomica*; so that in case of poisoning by that article, the same mode of treatment is to be pursued as in poisoning by nux-vomica or strychnia. "Nux-vomica bark (kuchila) is commonly sold in Calcutta for rohun, the harmless bark of *Soymida febrifuga*—a most dangerous substitution." (Pereira.)

Notwithstanding the "Act to regulate the Sale of Poisons" in this country, *nux-vomica*, compounded in various ways, is too freely sold, and used for nefarious purposes.

In cases of poisoning by *nux-vomica*, the most prompt treatment is necessary, and still more so if any of the soluble salts of strychnia have been taken. "Nux-vomica is occasionally made the instrument of voluntary death, although no poison causes such torture." (Christison.) The stomach-pump should instantly be had recourse to, when nux-vomica has been taken in powder; and as it adheres very obstinately to the coat of the stomach, it must be perseveringly used, with plenty of water. Emetics are too tedious in their action to be depended upon. M. Donné has recommended, when strychnia or any of its salts have been taken, to endeavour to form an insoluble salt; and for this purpose proposes chlorine, bromine, or iodine. The tincture of iodine may be procured promptly, but if ten minutes elapse before it be administered, it is unavailing. When the quantity of strychnia taken is not large, nor the symptoms very urgent, vital stimulants or sedatives are often sufficient; and for this purpose, wine, brandy, or a mixture of acetous ether and laudanum, or laudanum alone, will remove the present danger. Chloroform is sometimes successful, as is also ice applied along the spine. Conium or its tincture offers probable means of antagonising the action of strychnia, as suggested by Dr. Pereira. It is said that the leaves of the *Feuillea cordifolia* furnish an antidote to nux-vomica and several other vegetable poisons. It must ever be remembered that the danger is not entirely removed, though the spasms may have subsided, and the respiration become easy. Inflammation of the stomach may supervene, which will require the usual treatment, or secondary asphyxia may steal on, and destroy the patient. To prevent this last occurrence, great watchfulness is necessary, especially during the night, and the patient should be frequently awakened, and made to drink freely of green tea. But perhaps the most potent and efficient antidote to the other poisonous strychnias would be the urari poison of South America, as suggested by Mr. Morgan. (See Morgan's 'Lecture on Tetanus,' p. 31.) The preparation of this substance, which has been an object of curiosity and interest since the time of Sir Walter Raleigh, has been fully detailed by Sir Robert Schomburgk. ('Annals of Natural History,' vol. vii.) It is an article of much importance to the natives of Guiana, as much of their means of subsistence depends upon their possessing this poison, in which to dip their arrows for the chase. The chief, if not the only, active ingredient is the *Strychnos toxifera* (Schom.), and perhaps, in some places, *Strychnos cogens* (Bentham), the other ingredients (most of which are obtained from climbing plants, lianos, or "nebbees," except one bulbous plant, a cissus, and another supposed to belong to the *Xanthoxyleæ*) are used only to bring the juice to a proper degree of consistency and adhesiveness. Arrows dipped in it have been known to retain their poisonous properties for twenty-seven years. (Iliff, in 'Medical Gazette,' vol. xx., p. 261.) The poison when inspissated may be rendered liquid by heat, and is soluble in water, in alcohol, in hydrochloric acid, and in volatile alkaline spirit. It unites with acids without commotion or change of colour. If it be united with alkalies, no ebullition is observable, but it changes its colour from a dark brown to a yellowish-brown. It possesses a remarkable influence over the blood after it is taken from a vein. "A few grains, mixed with as many ounces of human blood warm from the veins, entirely prevents a separation of serum and crassamentum, and the whole mass continues in a state of fluidity similar to that in which it was drawn, until, after some days, it putrifies." (Bancroft.) This property seems to point out the propriety of employing it in cholera, in which the separation of the serum from the crassamentum, while the blood is yet in the body, is one of the most remarkable symptoms of that disease. Dr. Hancock is of opinion that it is one of the most potent sedatives in nature, and, could it be safely managed, he had no doubt it might become a valuable remedial agent in the treatment of spasmodic or convulsive disorders. Its taste is an agreeable bitter, and it has a tonic and febrifuge effect, frequently proving a valuable cure in intermittents. It, as well as the venom of the viper, seems to be disarmed of its virulence by undergoing the process of digestion.

On account of the difficulty of preparing the alcoholic extract of *nux-vomica* of uniform strength, strychnia, or some of its soluble salts, is now generally substituted for it, as these admit of easy subdivision of the dose. Sulphate of strychnia has been used in some cases with great advantage (See Gaskoin, in 'Med. Gaz.,' vol. x., p. 316); so also the acetate; but a form of preparation which has proved of service in some long-standing and almost hopeless cases of paralysis, is the hydriodate of strychnia. (See Magendie, 'Formulaire.') Phosphate is also used; and in Germany nitrate is much used.

Care must be taken that the strychnia be pure, as a spurious article is vended in France, which contains no trace of strychnia. Bichloride of mercury is a good test for strychnia, but it causes no precipitate from the solution of the acetate of strychnia; but the addition of hydrochloric acid causes a white crystalline precipitate. Sulphocyanodide of potassium appears to be the best test for strychnia. (See 'British Annals of Medicine,' vol. i., p. 190.)

Strychnia is prepared either from the *nux-vomica* seeds, in which case it is difficult and expensive to separate it from the brucia, or it is obtained from the St. Ignatius bean, in which it exists in about three times larger quantity than in *nux-vomica*. It is also, but rarely, procured from the *Strychnos Colubrina*. The purest and most easily obtained is furnished by the *Strychnos Tieuté*, but the rarity of this substance is a practical obstacle to its employment. Igasurina will probably be found to act like the others, but more mildly.

Snake-wood.—Many substances, in countries infested with serpents, are reputed to be efficacious in counteracting the poisonous bites of these reptiles: one of the most celebrated of these is the root of the *Strychnos Colubrina*. The strychnia probably acts as an antagonist to the stupifying effects of the poison of the snake, just as arsenic does to the poison of the *Coluber carinatus* of the West Indies. [ARSENIC.]

Strychnos potatorum, called also *S. Tettan Cottay*, or Clearing-nut, is a native of India, and is a larger tree than any other species. It is devoid of noxious properties. The fruit, though when very young it is made into a preserve, and eaten, is reckoned emetic by the native doctors. The chief use made of it is to rub the seeds hard round the inside of an earthen pot, into which water is poured, and in a short time it becomes clear, tasteless, and wholesome, however muddy, brackish, or putrid it may have been: hence its name of clearing-nut. Officers and soldiers, before setting off on a march, provide themselves with a store of these, as water purified by such means is deemed more wholesome than that clarified by alum.

Strychnos pseudo-china, Quina do Campo, or Field China, is a native of Brazil (St. Hilaire, 'Plantes Usuelles de Brésil,' t. 1), and is devoid of strychnia or brucia. It is a remedy of the Sertaneias, being peculiarly fitted for those cases to which the true cinchonas are unsuitable. The taste is at first faintly aromatic, then astringent, and at last slightly bitter. It has no odour. In its properties it resembles quassia, menyanthes, or gentian more than the true cinchonas, with none of which, except the humalia bark, could it readily be confounded in its physical characters. Mr. Burchell says, however, that even in the proper localities of the cinchonas many strychni are collected. [CINCHONA, in NAT. HIST. DIV., col. 1081.]

STUCCO. A name sometimes, though incorrectly, applied to all descriptions of lime or cement renderings on masonry, whether external or internal, but which is really given by builders to a species of plastering, in ordinary cases worked up by hand to a fine face adapted to receive paint; or in superior buildings made by the addition of other materials than the lime, or plaster, usually employed, in order to resemble marble. Common stucco, in fact, is nothing more than plastering which has received an additional amount of manipulation; marble stucco is made with fine lime (composed of the pure hydrate of that base) mixed with calcareous powder, chalk, or other analogous substances in such proportions and worked in such manner as to produce a hard, uniform surface, which admits of being coloured, painted, and polished so as to represent valuable marbles. It is employed in decorative architecture to cover columns, pilasters, walls, cornices, plinths, &c., in sheltered or covered positions: in external works, the natural or the artificial calcareous cements, or the oleaginous cements, are employed for this purpose—a distinction unknown by the Italians who first used the "stucca tura," from whence we have derived the art, and the name, of the fine plastering used by us exclusively for decorative and internal works.

Uniform marble stucco is prepared by mixing pounded white Carrara marble, or gypsum in the form of the white alabaster, with rich lime carefully slaked and run through a sieve, and the mixture is trowelled on to a rough rendering coat until the surface is perfectly even and homogeneous. Different colours are communicated by the addition of the metallic oxides, and when very delicate tints are required plaster mixed or gauged with water containing size, fish-glue, or gum arabic, is substituted for the hydrate of lime. The polishing is only commenced when the surface is perfectly dry, and it is effected by the use of fine grits, tripoli powder, chalk, and oil; very much in the same manner that marble is polished. Scagliola is executed with the same class of materials as the marble stuccos; but small splinters (or *scagliole*) of the marble desired to be imitated, should the latter present much variety of effect, are introduced in the finishing coats. Of late years the Keene's and the Parian cements have been exclusively used in London, instead of the ancient marble stuccos.

STURM'S THEOREM. There is a branch of the theory of equations, containing the celebrated theorems of Descartes, Fourier, and Sturm, which it is advisable to place in an article by itself, and the present heading has been chosen because Sturm's theorem is at once the most conclusive and the latest of the three. It has long been a problem of much interest and notoriety to find, in a given equation, how many roots, if any, are contained between two given limits; how many roots are positive, how many negative, how many imaginary.

The first step towards the solution of the preceding problem was made by Descartes, though it is asserted by Cossali and Libri, that Cardan came very near to the same step. Cossali, after collecting a table of Cardan's cases, and putting them in a form which Cardan did not use (an equation with 0 on the second side), then says that an analyst who should look at this table would be able to rise to Descartes's theorem. This is true enough, but it does not prove that Cardan either could or did make the invention, but the contrary. All the world knows that mathematical discoveries are recognised often enough by analysts of a later day, in rudiments from which the fabricators of them could evolve nothing.

The theorem of Descartes, expressed in his own words, is as follows ('Geometria,' lib. iii.): "Ex quibus etiam cognoscitur, quot veræ et quot falsæ radices in unaquaque Æquatione haberi possint. Nimirum, tot in ea veras haberi posse, quot variationes reperiuntur signorum + et −; et tot falsas quot vicibus ibidem deprehenduntur duo signa +, vel duo signa −, quæ se invicem sequuntur." That is, that an equation may have as many positive roots as there are changes of sign in passing from term to term, and as many negative roots as there are continuations of sign; but not more of either kind. It has been doubted whether Descartes knew the true meaning of his own theorem as to the case of imaginary roots; this doubt is as early as the time of Descartes himself, who replies in a letter which we cannot find by means of Rabuel's reference to it. This is however of little consequence, as the following sentence (also from the Geometry) shows in what manner Descartes understood his own words: "Cæterum radices tam veræ quam falsæ non semper sunt reales, sed aliquando tantum imaginariæ; hoc est, semper quidem in qualibet Æquatione tot radices quot dixi, imaginari licet; verum nulla interdum est quantitas quæ illis, quas imaginamur, respondet." It would seem then that Descartes not only remembered the limitation of the theorem arising from the possible existence of imaginary roots, but proposed to divide those last roots themselves into two classes corresponding to the true and false (or positive and negative) of the real roots. The next step was made by De Gua (1741), who showed that the roots of an algebraical equation $\phi\,x=0$ are never all real, unless the roots of the derived equations $\phi'\,x=0$, $\phi''\,x=0$, &c. be also all real; $\phi'\,x$, $\phi''\,x$, &c. being the derived functions, or differential coefficients, of $\phi\,x$. He also showed how to determine the conditions of the reality of all the roots. (Lagrange, 'Res. des Equ. Numer.', note viiii.; Peacock, 'Report,' &c., p. 327.)

Descartes's theorem would be perfect if the roots of equations were always real. For example, take $x^2-13x+40=0$. If the roots be real, they are both positive; write $x+6$ for x [INVOLUTION AND EVOLUTION], and we have $x^2-x-2=0$, of which the roots are less by 6 than those of the former equation. But in the second equation, one root is negative and one positive; consequently the roots of the first equation are one greater and one less than 6. In the same manner a more complicated case might be treated.

The theorem of Descartes, and the notion derived from it, that the order of signs of coefficients regulates the signs of the roots; with the step made by De Gua, and the notion derived from it, namely, that the derived functions must be consulted upon the question whether the roots of an equation be real or not; and the common theory of equal roots, namely, that when $\phi\,x=0$ has m equal roots, $m-1$ of its derived functions (neither more nor fewer) vanish at the same time, or with the same root,—were the hints on which FOURIER [BIOG. DIV.] was able to make an advance upon his predecessors. The coefficients of the equation are themselves nothing but the *divided* derived functions on the supposition that $x=0$. Thus, if $\phi x = 3x^3 - 7x^2 + 11x + 4$, we have

$$\phi 0=4,\quad \frac{\phi'0}{1}=11,\quad \frac{\phi''0}{1.2}=-7,\quad \frac{\phi'''0}{1.2.3}=3.$$

Let ϕx, $\phi_1 x$, $\phi_2 x$, &c. be the function in question, and its divided derived functions. If we make x great enough and negative (say infinite and negative), the signs of these functions are all alternate, that is, the series yields nothing but changes of sign in passing from term to term. But if we make x great enough and positive (say infinite and positive), the series yields nothing but permanences of sign. Thus, in the preceding expression we have

	$x=-\infty$	$x=0$	$x=+\infty$
ϕx	−	+	+
$\phi_1 x$	+	+	+
$\phi_2 x$	−	−	+
$\phi_3 x$	+	+	+
	nothing but changes.	two changes.	no changes.

$\phi x=3x^3-7x^2+11x+4$, $\phi_1 x=9x^2-14x+11$, $\phi_2 x=9x-7$, $\phi_3 x=3$.

Now Descartes's theorem tells us that there *may* be *one* negative and *two* positive roots, and we see that in passing from $x=-\infty$ to $x=0$, or through the whole range of negative quantity, there is *one* change of signs lost; while in passing from $x=0$ to $x=+\infty$, or through the whole range of positive quantity, *two* changes of sign are lost. Fourier's theorem would suggest itself as highly probable to any one who put Descartes's theorem in the preceding form: it is as follows:—When $x=a$, let the signs of ϕa, $\phi_1 a$, $\phi_2 a$, &c. be ascertained, and let this be called the criterion series, or simply the criterion. Then in passing from $x=a$, the less, to $x=b$, the greater (greater and less being understood in the algebraical sense), the criterion never acquires changes of sign, though it may lose them. When m changes of sign are lost to the criterion in passing from $x=a$, the less, to $x=b$, the greater, it follows that there are either m real roots of the equation lying between a and b, or some number, p, of pairs of imaginary roots, and $m-2p$ real roots lying between a and b. If m be odd, there must be at least one real root lying between a and b. And if no changes of sign be lost in passing from a to b, there is certainly no root lying between a and b. For example, examine the preceding function and its derivatives when $x=-1$ and $x=+1$. In the former case the criterion is − + − + (three changes), and in the latter + + + + (no changes). Three changes then are lost to the criterion in passing from −1 to +1: so that there are either three real roots, all lying between −1 and +1; or one such real root and two imaginary roots. Again, in passing from −1 to 0, one change is lost: there is certainly then one negative root between −1 and 0. The remaining roots are then either both imaginary, or positive and lying between 0 and 1: the least consideration of the equation will show that the former is the case.

Fourier's theorem is proved as follows:—changes of sign take place only when quantities become nothing or infinite; those before us cannot become infinite, and therefore the criterion can never be disturbed except when one or more of the set ϕx, $\phi_1 x$, &c. vanish. Now when any function ψx, vanishes, say at $x=a$, its previous sign must have been the contrary of that of its derived function, and its subsequent sign the same; that is, in passing from $a-h$ to $a+h$, h being very small, $\psi' x\times\psi x$ must pass from negative to positive. An algebraical proof may be given of this, but none which in brevity comes near to the following. The function $\psi' x\times\psi x$ is the derived function or differential coefficient of $\frac{1}{2}(\psi x)^2$, a positive quantity. Now if $\psi a=0$, $\frac{1}{2}(\psi x)^2$ must diminish (being positive) from $x=a-h$ to $x=a$, and increase from $x=a$ to $x=a+h$. But a differential coefficient is negative when its function diminishes with an increase of the variable, and positive when its function increases with an increase of the variable. Consequently $\psi' x\times\psi x$ is negative from $x=a-h$ to $x=a$, and positive from $x=a$ to $x=a+h$; as asserted. We now proceed to the proof of the theorem.

1. When $x=-\infty$, the criterion is + − + − &c. or − + − + &c.; and when $x=+\infty$, it is + + + &c. or − − − &c. This follows immediately from the nature of the functions ϕx, $\phi_1 x$, &c., in which, when x is numerically great enough, the sign is always governed by that of its highest term. Thus, in some place or places, so many changes are certainly lost as there are units in the dimension of ϕx, *neither more nor fewer*, unless changes be gained and afterwards lost.

2. When x passes through a root of ϕx, as many changes are lost as there are roots of ϕx equal to that root. Let there be only one root equal to a, so that $\phi_1 a$ does not vanish. We have then one or other of the following:—

	$x=a-h$	$x=a$	$x=a+h$		$x=a-h$	$x=a$	$x=a+h$
ϕx	(+)	0	(−)	ϕx	(−)	0	(+)
$\phi_1 x$	−	−	−	$\phi_1 x$	+	+	+
	One change lost.				One change lost.		

The signs in parentheses are those which follow from the theorem above proved. $\phi_1 x$ cannot change its sign in the process, for by hypothesis it does not vanish when $x=a$, and we take h so small that there shall be no root of $\phi_1 x$ between $a-h$ and $a+h$. At $x=a-h$, we must have $\phi_1 x\times\phi x$ negative, and at $x=a+h$ we must have it positive, by the theorem; which gives the signs in parentheses as marked.

Now let there be, say five roots equal to a, or let ϕa, $\phi_1 a$, $\phi_2 a$, $\phi_3 a$, $\phi_4 a$ all vanish, $\phi_5 a$ not vanishing. We must have then one or other of the following:—

	$x=a-h$	$x=a$	$x=a+h$		$x=a-h$	$x=a$	$x=a+h$
ϕx	+	0	−	ϕx	−	0	+
$\phi_1 x$	−	0	−	$\phi_1 x$	+	0	+
$\phi_2 x$	+	0	−	$\phi_2 x$	−	0	+
$\phi_3 x$	−	0	−	$\phi_3 x$	+	0	+
$\phi_4 x$	+	0	−	$\phi_4 x$	−	0	+
$\phi_5 x$	−	−	−	$\phi_5 x$	+	+	+
	Five changes lost.				Five changes lost.		

All the signs except those in the lowest line are dictated by the preliminary theorem. Thus $\phi_5 x$, in the first case, is negative by hypothesis; now $\phi_5 x$ is $\phi'_4 x\div 5$, so that $\phi_5 x\times\phi_4 x$ must be negative before $\phi_4 x$ vanishes, and positive afterwards. Hence $\phi_5 x$ continuing negative, $\phi_4 x$ must change from positive to negative. Again, $\phi_4 x\times\phi_3 x$ makes a similar change. The least consideration will show that, the signs in the lowest line being given, those in all the upper ones must be as written.

3. When intermediate functions vanish, changes of sign are never gained, but only lost; and are never lost but in even numbers. Suppose, for instance, that $\phi_1 a$ vanishes, but not ϕa nor $\phi_2 a$. We have then one of the four following:—

	$x=a-h$	$x=a$	$x=a+h$		$x=a-h$	$x=a$	$x=a+h$
ϕx	+	+	+	ϕx	−	−	−
$\phi_1 x$	+	0	−	$\phi_1 x$	+	0	−
$\phi_2 x$	−	−	−	$\phi_2 x$	−	−	−
	No change lost.*				*Two* changes lost.		
ϕx	−	−	−	ϕx	+	+	+
$\phi_1 x$	−	0	+	$\phi_1 x$	−	0	+
$\phi_2 x$	+	+	+	$\phi_2 x$	+	+	+
	No change lost*				*Two* changes lost.		

The signs in the middle lines are dictated by the preliminary theorem. Next let $\phi_4 a$, $\phi_5 a$, $\phi_6 a$, $\phi_7 a$ vanish, but not $\phi_3 a$ nor $\phi_8 a$. We have then, by the preliminary theorem, one or other of the four following:—

	$x=a-h$	$x=a$	$x=a+h$		$x=a-h$	$x=a$	$x=a+h$
$\phi_3 x$	+	+	+	$\phi_3 x$	−	−	−
$\phi_4 x$	−	0	−	$\phi_4 x$	−	0	−
$\phi_5 x$	+	0	−	$\phi_5 x$	+	0	−
$\phi_6 x$	−	0	−	$\phi_6 x$	−	0	−
$\phi_7 x$	+	0	−	$\phi_7 x$	+	0	−
$\phi_8 x$	−	−	−	$\phi_8 x$	−	−	−
	Four changes lost.				Four changes lost.		
$\phi_3 x$	−	−	−	$\phi_3 x$	+	+	+
$\phi_4 x$	+	0	+	$\phi_4 x$	+	0	+
$\phi_5 x$	−	0	+	$\phi_5 x$	−	0	+
$\phi_6 x$	+	0	+	$\phi_6 x$	+	0	+
$\phi_7 x$	−	0	+	$\phi_7 x$	−	0	+
$\phi_8 x$	+	+	+	$\phi_8 x$	+	+	+
	Four changes lost.				Four changes lost.		

* Observe that in these cases a change is removed to a higher place in the series, nearer to the head of the criterion.

The same conclusions will be found from other cases, and we have now examined every way in which the criterion can undergo an alteration in the order of the signs of which it is composed. And since, the function being of n dimensions, there are altogether n changes, and n only, to lose, it follows that every pair of signs lost by the vanishing of any of the derived functions, in any internal part of the criterion, shows that there must be two imaginary roots: for there must be n roots only, every real root must be accompanied by a change lost at the head of the criterion, and every loss of changes which takes place anywhere else diminishes the number which can take place at the head. Again, since losses other than at the head of the criterion must take place in even numbers, it follows that of any odd number of losses, one must have been effected at the head, or must have risen from a real root; or if not one, some other odd number.

The manner in which the changes of sign take place is as follows:— When $x=-\infty$, or even when it is numerically greater than any negative root, the criterion presents nothing but changes. Alterations of the criterion consist in: 1, Loss of one or more changes at the head of the criterion (showing real roots); 2, loss of changes in even numbers in the middle of the criterion (showing imaginary roots); 3, elevation of changes, or alteration of their place in a direction towards the head of the criterion. This last takes place only when an *odd* number of derived functions vanishes, the including functions (preceding and following) having different signs. So soon as a root has been passed, there is a permanency + + or − − at the head of the criterion; before another root is arrived at, this permanence must have become a change, since a change there must then be at the head to be lost in passing through the root. Hence it follows that between two roots of $\phi x=0$, there must lie a root of $\phi' x=0$; and this root is either single, triple, quintuple, &c., but not double, quadruple, &c.

For example, let $\phi x=x^4-7x^3+15x^2-10x+2$,

$\phi_1 x=4x^3-21x^2+30x-10$, $\phi_2 x=6x^2-21x+15$,

$\phi_3 x=4x-7$, $\phi_4 x=1$.

There are no negative roots, as is obvious from their being nothing but changes among the co-efficients; if we construct the criteria for $x=0, 1, 2, 3$, and 4, we find the following results:—

	0	1	2	3	4
ϕx	+	+	+	−	+
$\phi_1 x$	−	+	−	−	+
$\phi_2 x$	+	0	−	+	+
$\phi_3 x$	−	−	+	+	+
$\phi_4 x$	+	+	+	+	+

When $x=0$, the criterion shows four changes; at $x=1$, it is indefinite, owing to $\phi_2 1=0$. But immediately before $x=1$, $\phi_2 x$ must, by the preliminary theorem, have the sign contrary to that of $\phi_3 x$, or the sign +; consequently, for $x=1-h$, however small h may be, the criterion must be + + + − +. Two changes of sign are therefore lost in passing from $x=0$ to $x=1$, and there are either two real roots between 0 and 1, or two imaginary roots. To try this further, let $x=\frac{1}{2}$, the criterion of which is − + + − +; so that there is one root between 0 and $\frac{1}{2}$, and another between $\frac{1}{2}$ and 1. When $x=1+h$, the criterion is + + − − +, so that there is no root between 1 and 2. Lastly, there is one root between 2 and 3, and one between 3 and 4.

The theorem of Fourier, though very convenient in practice, is defective in theory, as requiring an indefinite number of trials. If two roots were very nearly equal, it would require very minute subdivision of the interval in which they are first found to lie, to distinguish them from a pair of imaginary roots. This theorem was not published till 1831, in Fourier's posthumous work, but its author had made his methods known, and among others to the late M. Sturm, a young Genevese, employed in the bureau of M. de Férussac, editor of the bulletin which bore his name, afterwards a member of the Institute, who died a few years ago. Sturm applied himself to the detection of functions which should stand in the place of ϕx, $\phi_1 x$, $\phi_2 x$, &c., in such manner that the criterion formed from them, in the same way as in Fourier's theorem, should never lose a change of signs except in passing through a real root. In this he signally succeeded; and thus, though his theorem presents great practical prolixity of detail, he furnished a complete solution of the difficulty which had occupied analysts since the time of Descartes. This theorem may be proved as follows:—

Let there be any number of functions $V, V_1, V_2, \ldots V_r$, the last of which is a constant independent of x, and all but the last are functions of x. Let them be connected together by the equations—

$$\begin{aligned} V &= P_1 V_1 - V_2, \\ V_1 &= P_2 V_2 - V_3, \\ V_2 &= P_3 V_3 - V_4, \\ &\cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot \\ &\cdot\quad\cdot\quad\cdot\quad\cdot\quad\cdot \\ V_{r-2} &= P_{r-1} V_{r-1} - V_r. \end{aligned}$$

$P_1 P_2$, &c., being any functions of x, which do not become infinite when $V_1 V_2$, &c., vanish. From this it follows, first, that no two consecutive functions of the set V, V_1, &c., can vanish together; for if V_2 and V_3, for instance, vanished together, the third equation shows that V_4 would also vanish, the fourth that V_5 would vanish, and so on; consequently V_r, a given constant, also vanishes, which is absurd. Secondly, when any one after V vanishes, the preceding and following must have different signs; for $V_1=0$ gives $V=-V_2$, $V_2=0$ gives $V_1=-V_3$, &c. Now call the signs of V, V_1, &c., the criterion, and let $V=0$ when $x=a$, there being only one root of that value, so that V changes sign in passing from $x=a-h$ to $x=a+h$. Since V_1 does not vanish with V, we have one of the four cases following:—

	$x=a-h$	$x=a$	$x=a+h$	$x=a-h$	$x=a$	$x=a+h$
V	−	0	+	+	0	−
V_1	−	−	−	−	−	−
V	−	0	+	+	0	−
V_1	+	+	+	+	+	+

If V_1 be the derived function of V, only the second or third cases can happen, by the theorem so often used in the preceding part of this article; so that a change of sign will be lost at the head of the criterion for every single root of $V=0$. Nor will any change of sign ever be gained or lost in any other manner; for suppose $x=a$ gives $V_4=0$ for instance, then V_3 and V_5 have different signs, and in passing from $x=a-h$ to $x=a+h$, if each be so small that no root of V_3 or V_5 lies between $a+h$ and $a-h$, we must have one of the following cases:—

	$x=a-h$	$x=a$	$x=a+h$	$x=a-h$	$x=a$	$x=a+h$
V_3	−	−	−	+	+	+
V_4	±	0	±	±	0	±
V_5	+	+	+	−	−	−

In no one of these is any change of sign lost, or anything except a change and a permanence when $x=a-h$, and a change and a permanence, in a different order perhaps, when $x=a+h$. Consequently, if in passing from $x=a$, the less, to $x=b$, the greater, it appear that no changes of sign are lost, it is certain that there must have been no real roots of $V=0$ between $x=a$ and $x=b$.

Now, V_1 being the derived function of V, it remains to find V_2, V_3, &c. Divide V by V_1, which is of one dimension lower, and we have a quotient, say P_1, and a remainder R_1. Then $V=P_1\ V+R$ or $V_2=-R$. Again, divide V_1 by V_2, giving a quotient P_2, and a remainder R_2: we have then $V_1=P_2\ V_2+R_2$ or $V_3=-R_2$; and so on. It appears, then, that V_r, being the derived function of V, we must proceed as in finding the greatest common measure of V and V_1, only changing the sign of every remainder as fast as it is obtained. In order that the last, V_r, may be a finite constant, it is requisite that there should be no equal roots. We must then suppose the equal roots to be separated beforehand, as in the usual method. In fact, this very process of finding the greatest common measure, with or without change of sign in the remainders, will first detect the equal roots, if any. It is important to remark, that at any step multiplication by any positive quantity is allowable, the signs (the only things we have to do with) not being in any case altered by such multiplication.

In INVOLUTION AND EVOLUTION a method of performing the operations required in Sturm's theorem was proposed, which avoids useless writing. Mr. Young ('Math. Dissertations,' p. 143) proposed another, of much the same degree of abbreviation. Sturm's theorem however requires so much operation, that there can be little doubt of that of Fourier being a more easy mode of working any particular case. It is not however as a key to the mere numerical solution of equations that either of these theorems must be viewed: the insight which they give into the nature of equations, and still more that which they are likely hereafter to give (for neither is more than a germ), will render them both important steps in the progress of algebra.

Since it is sufficient to the theorem that the last function V_r should retain one sign, and not vanish, we may stop in the process when we arrive at any function of which all the roots are known, or can be discovered, to be impossible. And it is easily shown, as was done by Sturm himself, that even when there are equal roots, so that the last, V_r, is neither constant nor always of the same sign, the theorem still remains true, so far as to give the number of *different* roots which lie between any two given limits, without any information as to the number of times which each root should be repeated.

For instance, in the article cited we find

$$\begin{aligned} V &= x^4-3x^3-2x^2+x-3 \\ V_1 &= 4x^3-9x^2-4x+1 \\ V_2 &= 43x^2+45 \end{aligned}$$

We need not go further, for V_2 has none but imaginary roots. Now when $x=-\infty$, the criterion is + − +; when $x=0$, it is − + +; and when $x=+\infty$, + + +. Consequently there is one negative root, one positive root, and a pair of imaginary roots.

The following example is from Mr. Young (p. 191): it is an instance given by Fourier in illustration of his own method, and Sturm's is applied to it by Mr. Young, to show the superior certainty of the latter. Of that certainty no one can doubt, but the process exhibited in the page cited is such as will never come into general use unless the work can be made more easy:—

$$\begin{aligned}
\mathrm{v} &= x^7-2x^5-3x^3+4x^2-5x+6\\
\mathrm{v}_1 &= 7x^6-10x^4-9x^2+8x-5\\
\mathrm{v}_2 &= 2x^5+6x^3-10x^2+15x-21\\
\mathrm{v}_3 &= 62x^4-70x^3+123x^2-163x+10\\
\mathrm{v}_4 &= -4403x^3+8862x^2-19810x+20531\\
\mathrm{v}_5 &= 200865x^2+489790x-1169472\\
\mathrm{v}_6 &= 187355x-270632\\
\mathrm{v}_7 &= \text{a positive constant.}
\end{aligned}$$

Here the criteria for $x=-\infty$, $x=0$, $x=+\infty$ are

$$\begin{array}{lll}
x=-\infty & -+-+++-+ & \text{five changes}\\
x=0 & +--++--+ & \text{four changes}\\
x=+\infty & ++++-+++ & \text{two changes.}
\end{array}$$

There are then one negative root and two positive roots, and therefore four imaginary ones. The reader will easily find that the positive roots lie between 1 and 2, and the negative root between -1 and -2. The exhibition of the process, leaving out the actual performance of multiplications, has 400 figures in Mr. Young's work. Fourier has merely written down the derived functions, which is done at sight, and formed the criteria for $x=-10$, $x=-1$, $x=-h$, $x=0$, $x=+h$, $x=1$, $x=10$, which may all be done at sight also. From this he finds that there must be one negative root between -1 and -10, that there may be two roots between 0 and 1, and two more between 1 and 10. All this might be done before v_4 could be found and written down as above. It is to be hoped either that Fourier's theorem will be completed by the addition of a test for imaginary roots, or that Sturm's functions will be exchanged for others of less complicated operation. But in the meanwhile it must be remembered that Fourier, Sturm, and Horner have completely changed the aspect of the solution of numerical equations: at the beginning of the period mentioned, it would have been thought too good to expect that any certain method of predicting, or easy one of calculating, the roots of such equations, should be found, after the failure of all analysts from Descartes and Newton down to Euler and Lagrange, the best heads of France and England, Germany and Italy. It is a lesson against despairing of the attainment of any result, however illustrious the investigators who have not succeeded, and also against imagining that the hints of preceding ages are exhausted. All the contents of the present article arise out of a new mode of looking at the theorem which Descartes gave more than two hundred years ago.

STYLE, used for manner of writing, from the Latin *stylus*, the same word with the Greek *στύλος*, a "pillar," or "column." The Romans gave that name to an iron bodkin having a sharp point, with which they were accustomed to write by exaration, or scratching, on their wax-covered tablets or note-books; and from the instrument of writing, the term was transferred to the writing itself, and that too considered in reference not to the form of the characters (which would have been the more immediate transition), but to the mode of expression. Among the Romans, however, the term, in this figurative application of it, retained always considerably more of its antecedent meaning than it does with us. We say not only style of writing and style of speaking, but style of painting, style of architecture, style of dress, style of anything in which form or manner is conceived to be, in however slight a degree, expressive of taste or sentiment—if even this much of distinction still remains between what is called style and mere manner in the widest or loosest sense.

Style, in writing or speaking, may of course mean a bad style as well as a good style. Yet when the word stands alone, we always understand it in the latter sense—just as when we speak of expression in painting or in music we mean just or forcible expression. Thus, Swift has said, "Proper words in proper places make the true definition of a style." This, however, is merely to tell us, what is sufficiently obvious, that the art of expressing thought by language consists in two things: first, the selection of words; second, their collocation or arrangement. That to constitute a good style, both this selection and this collocation must be proper, there can be no doubt; the only question is, what constitutes propriety as to such matters. Style has been sometimes considered as nothing more than the image or outward expression of thought, as its produce or creation in the same sense in which it may be said that the impression upon the wax is the creation of the seal; and it has hence been assumed that all that is necessary for the ensuring of a style of any degree of excellence is the possession of a corresponding power of thought. But a little reflection will satisfy us that this is an insufficient explanation. Of two men equal in powers of mind, and equally in possession of a subject, nothing is more common than that the one should be able to expound it much more clearly and effectively than the other. Language is an instrument the use of which must be learned like that of any other instrument. Style is rather the vehicle than the mere expression of thought; and the thought may be present where the vehicle is wanting. To some extent, also, it may be said to be the dress of thought, or that which ornaments and sets off thought, not only by the added charms of sound, but by other powers which are inherent in words, and of which unexpressed thought knows nothing. As there are "thoughts that breathe," so there are "words that burn"—that by their associations excite impressions of the grand, the pathetic, or the humorous, whether they are addressed to the ear or merely to the eye. And great effects are also to be achieved by the arrangement of words, not only in the production of melody and cadence, but in a higher kind of gratification or excitement—as by the luminous disposition of all the parts of the sentence, by the presentment of every term at the place best fitted to bring out its whole import, by all the resources of what the grammarians call inversion, ellipsis, and other figures of speech; which, indeed, wherever they are properly used, are no deviations from natural syntax at all, but, on the contrary, the most natural forms that can be employed. For, while writing is an art, it is nevertheless most true that, like all the other arts the purpose of which is to give expression to mind, the guiding and controlling principle of its exercise, its life and being, as we may say, must ever be as exact and sympathetic a conformity as possible to the thoughts or emotions of the writer. Whatever more style is than the mere expression of thought, that much it must be at the least. A powerful thinker may not always be a powerful writer, but no man can be a powerful writer who is not a powerful thinker. Even the humblest quality of style, mere perspicuity, cannot be attained without a corresponding degree of clearness of thought. We sometimes meet with a perspicuity which is little more than grammatical, and hardly belongs to style at all; but even that implies distinct conceptions so far as they go—a limpid stream of thought, however little depth or spaciousness of intellect. And as for all higher attributes, it is manifest that they cannot be found in the style, if they do not exist in the mind of the writer. The only fountains from which a man's words can derive the animation of true passion, or poetry, or wit, must be his own head and heart.

The lowest kind of writing that deserves the name of a style at all (unless it is to be called a bad style) ought, as we have observed, to be perfectly perspicuous—that is to say, readily and completely intelligible in so far as the understanding of it depends merely upon a knowledge of the language. The subject may be a difficult one; but that is only a reason for more pains being bestowed to make the style clear and easy, by a lucid arrangement and the avoidance of all ambiguities of expression. But although this rule may be justly insisted upon where nothing beyond such perspicuity is desirable, it will not bear to be so rigidly enforced in regard to the higher kinds of style. Here some sacrifice even of perspicuity is at times to be submitted to, for the sake of appropriate effects which could not be otherwise attained. Æschylus, no doubt, might have made his chorusses, Pindar his odes, Tacitus his historic pictures, more easily comprehensible, better fitted for the use of such readers as would always run while they read, by greater diffuseness and dilution of style; but much more, certainly, would have been lost than gained by the attempt. What is to be desired in the highest kinds of writing, as in the highest creations of all the fine arts, is not perfect comprehensibility at a glance, but rather that fulness and profundity of meaning which can never be wholly comprehended, but supplies inexhaustibly something new to be seen and felt every time we return to the work.

In every cultivated language, however, the progress of style is decidedly towards more and more of first-sight intelligibility, in so far as that depends upon precision of phrase, and the use of words in certain limited meanings. This has been remarkably the history of the English language, at least for the last two hundred and fifty years, during which we have been fixing both our grammatical forms and our rules of syntax to an extent that would surprise most persons if the evidences of it were stated in detail. Whether all that has been done in this way has really improved the language,—whether it has been thereby rendered more expressive, more flexible, more fitted for the various ends which a language ought to subserve, may perhaps be questioned. The gain in point of precision may possibly be more than balanced by the loss both in ease and in variety of style.

In another respect, however, English prose eloquence has undergone a change of character in an opposite direction, by the greater infusion which it has received of a colloquial tone and phraseology within the last century and a half. Till towards the close of the 17th century, the language of books, except in the comic drama and other light compositions of a kindred character, generally preserved a formality of gait and manner which distinguished it nearly as much from living conversation as the critics have held that the language of verse should be distinguished from that of prose. Among the most eminent of the writers who first broke through this species of restraint were Cowley, in his Essays; Dryden, in his prefaces and other prose discourses; Sir William Temple; and the third Earl of Shaftesbury. The example set by them was followed by Swift, Addison, Steele, and their associates and imitators, till, in the earlier part of the last century, the colloquial ease and liveliness, which had thus become fashionable, threatened to degenerate into a slovenliness, or shambling fluency, alike without either elegance or precision. It must be admitted, that of all the writers of the second quarter of the 18th century, Lord Bolingbroke, whatever opinion may be entertained of his depth of thought or weight of matter, wrote the best style, at once the most flexible and idiomatic, and the purest, most refined, and most musical. But probably the writer who on the whole did most to restore measure and emphasis to our prose style was Johnson: his manner has not been much copied in all its peculiarities or in its entire character, but yet more or less of its influence may be detected in the style of nearly every one of the more remarkable writers who have subsequently appeared among us. At the same time, however, examples of altogether a different character were also producing their effects; and the rude vigour of Warburton, the *naiveté* of Sterne and Goldsmith, and, above all, the rapidity, variety, and imaginative splendour of Burke, have all operated powerfully in forming the greatest of our later writers. Finally, with all these influences have mingled and co-operated two others which have also been impulsive and generative to a considerable, though not both to the same, extent: on the one hand, the revived study of our old Elizabethan literature; on the other, the new life and spirit that has been put into literature, as into all things else, by the political and social convulsions of the last fifty years. These two influences, though thus apparently opposite in origin, have proved rather mutually assistant than contradictory.

Purity of style is more intimately connected with many apparently higher things than is commonly supposed. When it is considered, indeed, what the wrong use of a word springs from and implies, the mischief it is apt to occasion is easily understood. It is produced by a confusion of thought, which is propagated wherever the vicious mode of expression prevails, and which, besides the injury done in the particular case, helps generally to impair the habit and the faculty of clear and correct thinking. Yet words, for obvious reasons, have a strong tendency to shift their signification; if a language were to be merely spoken, and not written, this would be constantly taking place to a very great extent; the only thing that can check it, that can furnish a practically available standard of the language, is the employment of it in writing. Originally, indeed, the principles upon which it is written must be taken from its spoken form—from the *usus et norma loquendi;* but afterwards commonly the spoken language both will be and ought to be rather regulated and controlled by the written language. If it should continue to be otherwise, the language would not improve, but would degenerate towards barbarism; for there could be no progress in any other direction, in this or in anything else, where the comparative slovenliness and incorrectness of extemporaneous precipitation were allowed to carry it over the best efforts of deliberation and care.

STYLE, OLD AND NEW. By the Old Style is meant the mode of reckoning time anterior to the Gregorian reformation of the calendar; and by the New Style, that adopted since. The adoption of the reformation at different times by different countries renders it necessary to remember the difference of their reckonings, as follows:—

The reformation took place in 1582: from thence to the end of February, 1700, new style is *ten* days in advance of old style. Thus January 1 (O. S.) is January 11 (N.S.), and so on.

From and after March 1, 1700, to the end of February, 1800, new style is eleven days in advance of old style: thus January 1 (O. S.) is January 12 (N. S.).

The new style was adopted in England by 24 Geo. II. (1751), which enacted—1, that the year 1752 should begin on the 1st of January instead of the 25th of March, which was then the *legal* commencement; 2, that the 3rd day of September, 1752, should be called the 14th, or that the days from the 3rd to the 13th inclusive should have no nominal existence. Accordingly, the year 1751 had no January, February, nor March up to the 24th inclusive; and September wanted eleven complete days.

According to Sir Harris Nicolas, the new style was adopted as follows:—By Denmark, France, Holland, and most of the Low Countries (some towns excepted), most of Italy, Lorrain, Portugal, and Spain, in 1582; by German and Swiss Catholics in 1584; by Poland in 1586; by Hungary in 1587; by German and Swiss Protestants, and the remaining parts of Holland, &c., in 1700; by Tuscany in 1749 or 1751; and by Sweden in 1753. It is not yet adopted in Russia.

It was at one time sometimes the mode to express the date in both styles. We have an old letter written from France to Holland in 1619, as we should now call it, the date of which is Février $\frac{18}{28}$, $161\frac{8}{9}$. [Periods of Revolution.]

STYLOBATE. In its general meaning this term signifies any sort of basement upon which columns are placed to raise them above the level of the ground or floor; but in its technical meaning it is applied only to a continuous unbroken pedestal, upon which an entire range of columns stand—in contradistinction from *pedestals,* which are merely detached fragments of a stylobate placed beneath each column. The Greeks very rarely employed the stylobate, but placed their columns immediately upon the floor of the elevated platform of the gradini, or deep steps, which served as the basement of the temple, and which were generally continued on every side. [Grecian Architecture.] The Romans, on the contrary, broke up their stylobates into distinct blocks or pedestals placed beneath each column: and most followers of that or the Italian school have considered pedestals of that kind to be almost essential to an entire order, and have laid down proportions accordingly, which are in themselves exceedingly faulty, being much too high. At the best, columns upon detached pedestals always look as if placed upon stilts, and where such pedestals are as high as they are sometimes made, the columns seem to stand very insecurely, and the effect is very much like that of a round column immediately placed upon a dwarf square one.

STYPHNIC ACID. [Phenylic Group.]

STYPTICS (from στυπτικός, "astringent", agents which check the flow of the fluids, generally of blood, from a relaxed or ruptured vessel. They are a kind of astringent, and the principle of their mode of action has been already detailed. [Astringents.] The only point requiring notice here is to enforce the necessity of their prompt employment, as the natural disposition of the blood to coagulate becomes less and less as it continues to flow, till fainting be induced, and a cessation of the current results, after much injury is done to the system. The bleeding may be spontaneous, as is frequently the case with young persons, from whose nose blood frequently flows, even when perfectly quiet, but still more frequently when running or lifting some heavy weight, or it may be the consequence of a wound, such as a leech-bite, or of the extraction of a tooth, or caused by some cutting instrument. Those astringents are alone entitled to be called styptics which can be applied directly to the bleeding orifice; and of these some act chemically, others vitally, and others merely mechanically. Of chemical styptics, a saturated solution of alum, or sulphate of zinc, or creasote, are the best. Strong acetic acid acts both chemically and vitally. When blood continues to ooze from the socket of a tooth, it is a useful plan to plug it with a sponge-tent, which, as it expands, quite fills up the socket, and restrains the hæmorrhage.

A few drops of collodion upon a leech-bite, or the nap from a hat, or a spider's web, may be used.

STYRACIN. [Styrone.]

STYRACONE. [Styrone.]

STYRAX OFFICINALIS is the source of the officinal storax, although an article is occasionally vended under this name, which is obtained from the *Liquidambar styraciflua,* and perhaps other species of *Liquidambar,* yet in the London Pharmacopœia, it is said to be the produce of an unknown plant. Of genuine storax there are several varieties, and of those known to the ancients many are now altogether unascertainable, while of those mentioned by even recent writers several are very rare, and not of commercial importance. The tree grows in Greece and Asia Minor. Asiatic Turkey supplies whatever is met with in commerce. It is procured by incisions in the bark, or perhaps from the punctures of insects. What flows from these openings is a liquid resinous substance, which concretes into small tears, about the size of peas; these, aggregated into masses, constitute the *styrax albus,* which is of extreme rarity. Another form is that called *amygdaloides,* also of great rarity and extravagant price. It is sometimes termed *calamita vera.* The commercial article is of various degrees of purity and excellence. One kind is called *storax calamita vulgaris,* or *Scobs storacina.* This always contains more or less sawdust, mixed with variable quantities of resin. It is generally in large round cakes, of a brown colour, verging to red or black, with fragrant odour, brittle, and friable, but softens in the mouth, and has a bitter taste. It burns with a light flame. It is considered to be an artificial compound, prepared chiefly in Venice and Trieste. Liquid storax contains—volatile oil (styrol), a trace only; resin, both soft and hard, from 32 to 53 per cent. in different specimens; benzoic acid, from 1 to 2 per cent.; gum, 7 to 14; woody fibre, 20 to 27; ammonia, an inappreciable quantity; cinnamic acid and styracin.

Storax is stimulating in a degree dependent on its purity. For medical purposes it is directed to be purified by solution in alcohol, straining, and afterwards distilling off the spirit. The residuum is then used in a few preparations, such as tinctures and pills. It formerly entered into a multitude of compounds, but it might be altogether supplanted by benzoin. It is much used to form pastilles, and for fumigations. The bark is called *cortex thymiamatis,* or *cortex thuris,* from which, by boiling, liquid storax is procured, as well as from the *Liquidambar.* There is a storax from Bogota, but its source is unknown, though Geiger ascribes it to a styrax.

STYROL ($C_{16}H_8$). An essential oil existing in the gum resin, or balsam, of storax. [Balsams.] It is obtained on distilling a mixture of three parts of storax and one of carbonate of soda with water; and is purified by rectification after drying over chloride of calcium. It is colourless and limpid, has a persistent aromatic odour, and boils at 293° Fahr. It is isomeric with cinnamol or cinnamene, but is distinguished by being entirely solidified when heated suddenly to 400° Fahr. The solid is a polymeride of styrol and is termed *metastyrol,* or *draconyl,* the latter in allusion to another source, namely, dragon's blood resin (*Dracæna draco*).

Styrol is miscible in all proportions with alcohol or ether; is neutral, and has a density of 0·924. Sulphur and phosphorus are soluble in it. Nitric acid converts it into benzoic and nitrobenzoic acids; oily and resinous bodies being simultaneously formed. Chlorine and bromine form with styrol chloride and bromide of cinnamene.

Metastyrol is insoluble in water or alcohol, is only slightly soluble in ether, and has neither colour, odour, nor taste. It softens on the application of heat, and at a high temperature is reconverted into styrol. Nitric acid transforms it into *nitrometastyrol.*

STYRONE ($C_{18}H_{10}O_2 = \left.\begin{matrix}C_{18}H_9\\H\end{matrix}\right\}O_2$). *Cinnamic alcohol, Styracone, Peruvine, Cinnamyl-styrone* or *styracin,* or *metacinnamene* $\left(\left.\begin{matrix}C_{18}H_9\\C_{18}H_7O_2\end{matrix}\right\}O_2\right)$ is found in liquid storax and in balsam of Peru. On distilling either of the latter with strong caustic potash or soda, the styrone passes over along with water. On adding common salt to the water, a cream-like matter rises to the surface and gradually solidifies to an acicular mass of styrone. It melts when heated and boils at 482° Fahr. Its vapour has an agreeable odour resembling that of hyacinths: it rapidly attacks india-rubber. By peroxide of lead and caustic potash, or by chromic acid, styrone is oxidised to cinnamic acid. Under the influence of platinum black it is converted into the aldehyd of cinnamic alcohol $\left(\left.\begin{matrix}C_{18}H_7O_2\\H\end{matrix}\right\}\right)$ or hydride of cinnamyl, identical with the essential oil of cinnamon.

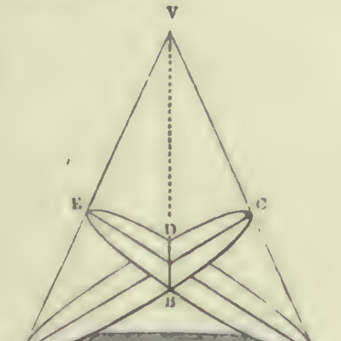
Styracin, or cinnamyl-styrone, is obviously polymeric with the hydride of cinnamyl just mentioned:—

$$\left.\begin{matrix}C_{18}H_9\\C_{18}H_7O_3\end{matrix}\right\}O_2 \quad = \quad 2\left(\left.\begin{matrix}C_{18}H_7O_2\\H\end{matrix}\right\}\right)$$

STYX (Στύξ or Στυγὸς ὕδωρ). In the ancient mythology the Styx was believed to be the principal river of the lower world, round which it flowed nine times. (Virg., 'Æn.,' vi. 439.) It was believed to be an arm of the river Oceanus, which flowed round our earth, and the river Cocytus was thought to be a branch of the Styx. When the gods of the ancients took a great oath, they always swore by the water of Styx, and awful punishment awaited him who swore falsely. The divinity of the river Styx was a nymph of the same name, daughter of Oceanus and Tethys, who dwelt at the entrance of the lower world in a spacious grotto supported by silver columns. (Hesiod, 'Theog.,' 778.)

SUB. A prefix applied in chemistry to a basic salt or to an oxide containing a less proportion of oxygen than a protoxide.

SUBCONTRARY. This word is particularly applied to the sections of a cone, in a manner which, without interfering with that application, would allow of its definition being generalised as follows:—When a figure or solid is symmetrical, so that equal lines or polygons can be drawn on two different sides, those equal lines or polygons may be called *subcontrary*. Thus, in Euclid, i. 5, the equal lines which are obliquely deflected from the two ends of the base of the isosceles triangle, are subcontrary. In a right cone every section has its subcontrary, except only the circle which generates the cone, and its parallels. Let V be the vertex of an oblique circular cone, and A B C D the circle on which it is described. Let the plane V A C be that which passes through the centre of the circle perpendicularly to its plane. Then the cone is exactly the same on one side of the plane V A C as on the other; and if a plane A G F be drawn through A perpendicular to the line which bisects the angle A V F, the section A G F is such that either half would take the place of the other, if it were to make a half revolution about A F. It is then an ellipse of which A F is one of the principal axes; and the middle point of A F, falling in the line which bisects A V F, is the centre. Consequently every section of this cone has a subcontrary section, except only those which are parallel to A G F. Hence the generating circle A B C D has a subcontrary circle E B F D, made by taking the line E F subcontrary to A C, and drawing through E F a plane perpendicular to the plane A V F. The angles V E F and V C A are equal, as also V A C and V F E.



In the limited use of the word subcontrary, no sections are considered in this light except the two circular sections of an oblique cone. Consequently, when subcontrary sections are mentioned, these circular sections are understood. The proofs given of the existence of these subcontrary sections usually conceal the fact of all cones described upon a circle being symmetrical when produced in every direction, and seem to make the existence of a second circular section a sort of accident of the circle, as if no other section had its subcontrary.

Since all parallel sections of a cone are similar, it follows that through every point of the surface two subcontrary circles can be drawn. The surfaces of the second order generally have the same property. [SURFACES OF THE SECOND ORDER.]

SUB-DOMINANT, in Music, the fourth of the key, mode, or scale. Thus, in the key of C, F is the sub-dominant.

SUBDUPLICATE, SUBTRIPLICATE. [RATIO.]

SUBERAMIDE. [SUBERIC ACID.]

SUBERANILIC ACID. [SUBERIC ACID.]

SUBERANILIDE. [SUBERIC ACID.]

SUBERIC ACID ($C_{16}H_{12}O_6 2HO$). An organic acid produced by treating rasped cork with diluted nitric acid; the cork is slowly dissolved, and a fatty substance is formed, which floats on the surface of the fluid. The solution is slowly evaporated till it thickens, and the residue is treated with about eight times its weight of water, by which an additional quantity of fatty matter separates. When the solution is filtered, suberic and oxalic acids separate, the former in the state of a white powder; this is to be saturated with ammonia, and the suberate of ammonia formed being decomposed by an acid, the suberic acid precipitates in the state of a white powder, which is to be washed with cold water. Suberic acid may also be obtained by treating margaric, oleic, or stearic acid with nitric acid. The properties of this substance are, that its acid powers are but feeble; it is very soluble in boiling water, and the greater part of it is deposited from the solution on cooling in the form of a white powder; it is soluble also in anhydrous alcohol; fuses at about 300°; and sublimes in acicular crystals.

The suberates are not an important class of salts; we shall therefore mention them briefly. Suberate of ammonia is soluble in water; the suberates of potash and soda are deliquescent, and fusible without decomposition: those of lime, baryta, strontia, magnesia, alumina, and manganese are more or less soluble; protosuberate of iron is a white precipitate; the persuberate is a brown one: the suberates of tin, zinc, mercury, and silver are white insoluble substances: that of cobalt is red, of copper blue-green, and uranium yellow.

By the distillation of suberic acid with excess of quicklime, a body termed *suberone* or *hydride of suberyl* ($C_{14}H_{12}O_2$) is produced. The following bodies are also derived from suberic acid:—

Suberamide	$C_{16}H_{16}N_2O_4$
Suberanilide	$C_{40}H_{24}N_2O_4$
Suberanilic Acid	$C_{28}H_{19}NO_6$

SUBERIC ETHER. [ETHYL.]

SUBERIN is a peculiar substance so named by Chevreul, as obtained from common cork, the epidermis of the *quercus suber*. When ten parts of cork have been treated with water, alcohol, ether, hydrochloric acid, potash, &c., there remain seven parts, which are suberin, possessing the following properties:—it is very inflammable; by distillation it yields water, a colourless oil, and afterwards a yellowish one, all of which are acid; then ammonia and a fatty crystallised substance are produced, and various gases are disengaged, while charcoal equal to one-fourth of the suberin remains in the retort. [CELLULOSE.]

SUBERONE. [SUBERIC ACID.]

SUBJECT, SUBJECTIVE. These words, with their correlatives Object and Objective, are now again restored to English philosophical language, through the medium of the German writers. The Subject is in philosophy invariably used to express the mind, soul, or personality of the thinker—the Ego. The Object is its correlative, and uniformly expresses anything or everything external to the mind; everything or anything distinct from it—the non-Ego. The universe itself, when considered as a unique existence, is an object to the thinker; and the very subject itself (the mind) can become an object, by being psychologically considered.

The distinction is most important. The exact distinction between the terms subject and object was first made by the schoolmen: for by the Greeks the word ὑποκείμενον was equivocally employed to express either the object of knowledge (the *materia circa quam*) or the subject of existence (the *materia in qua*). These correlatives, subject and object, correspond to the first most important distinction in philosophy, namely, the original antithesis of self and not-self. These terms, in their substantive and adjective forms, passed from the schools into the scientific language of philosophers.

SUBLIMATION, a chemical operation effected by the application of heat to certain bodies; it is essentially similar to distillation in principle, but differs from it in the nature of the substances to which it is applied. In distillation liquids are converted into vapour, and condensed into the same form by the cooling agency of water; whereas in sublimation solid bodies are vaporised, and afterwards reassume the solid state, in general merely by the cooling power of the air, without the assistance of cold water.

Sublimation is usually conducted in one vessel, the product being deposited in the upper part of it in a solid state, while the impurity remains in the lower. In small experimental researches a Florence flask answers perfectly well, and a good exemplification of the process is that produced by heating iodine in it: a purple vapour rises, which almost immediately condenses in small brilliant dark-coloured crystals in the upper part of the flask, the impurity remaining in the lower.

Sublimation is extensively employed, and for two different purposes; the simplest case is that of using it for purifying a substance, camphor for example, in which the pure camphor is vaporised, and condenses in the upper part of the vessel, while the impurities remain in the lower part.

In preparing corrosive sublimate and calomel, these substances are formed and sublimed by the same operation: in general large green-glass vessels, called *boltheads*, are used for calomel and corrosive sublimate; while for camphor very thin flint-glass vessels are used, which are called *bomboloes*, from the Italian *bombola*; in both cases a vessel is broken after each operation, to obtain the product. Among other substances procured by sublimation is benzoic acid, formerly called *flowers of benjamin*. This acid is sublimed in much larger vessels, and not usually made of glass; while the vapour of sulphur is condensed in a large chamber, or sulphur-house, and adheres to the walls in the form of a fine powder, known by the name of *sublimed sulphur*, or *flowers of sulphur*. [DISTILLATION.]

SUBLIME (Geometry). It may be worth while to state in few words, and to prevent a reader of the older mathematicians from imagining that they spoke rhapsodically, that the term *sublime geometry* was technical, meaning the higher parts of geometry, in which the infinitesimal calculus or something equivalent was employed.

SUBLIMITY has two significations: one, that of the quality or circumstance in objects, which raises the emotion named sublimity; the other, that of the emotion itself. The nature of the sublime, that is, those conditions of objects which invariably excite in us certain emotions, to which we give the common name of sublimity, is a subject of great interest and importance in psychology, and has always been a favourite subject of speculation. We shall briefly notice the more celebrated theories which have professed to embrace and explain all "those conditions which excite the emotions," and endeavour to point out their failures.

Longinus, whose work (Περὶ ὕψους) is the most ancient, treats only of the sublime in writing. His treatise was meant as a supplement to the work of Cæcilius on the 'Sublime,' in which he says Cæcilius brought a number of instances to show what is the sublime, as if every one did not know that well enough.

Burke's 'Inquiry into the Sublime and Beautiful' was the first attempt to give philosophical precision to our notions of the sublime. His theory is, that the essence of the sublime consists in terror operating either openly or latently; and the delight which is caused by this terror is referred to those principles of human nature which he calls "passions of self-preservation," and which turn on pain and danger. These passions "are simply painful when their causes immediately affect us; they are delightful when we have an idea of pain and danger, without being actually in such circumstances: this delight I have not called pleasure, because it turns on pain, and because it is different enough from any idea of positive pleasure—whatever excites this delight I call sublime." ('Inquiry,' part i., sect. 18.) "Whatever, therefore, is terrible, with regard to sight, is sublime too, whether this cause of terror be endued with greatness of dimensions or not." (Ibid., part ii., sect. 2.) Nothing can be more explicit than these two passages, nor more accurately exhibit the truth and error of his theory. The error is glaring in the second passage. Terror is often one feeling, exciting, in conjunction with other feelings, the emotion of sublimity, but not always. The stars are sublime, yet there is no terror in the emotion they excite. On the other hand there is a terror in a surgeon about to operate, or in a pedagogue about to flog—but no sublimity. The gallows is very terrible, but not at all sublime. Yet Burke was so chained down by his theory of terror being the ruling principle of the sublime, as to write—"There are many animals who, though far from being large, are yet capable of raising ideas of the sublime, because they are considered as objects of terror—as serpents and poisonous animals of all kinds." (Ibid., part ii., sect. 2.) Now, when a man asserts that a serpent is sublime, *because* it is terrible, it is evident that he uses the word sublime in a different sense from the rest of the world; otherwise we say a serpent is in no case sublime.

That the terrible is often a constituent of the sublime there can be no doubt, and Burke's error consists in seizing this occasional constituent, and declaring it to be the "ruling principle." And further, we must observe, that whenever a feeling of terror is found to be a constituent of the sublime, there will also invariably be found another feeling of security, correcting this terror. Thus, when we stand beneath a rock, the terror consists in a natural apprehension of its falling down and crushing us, which apprehension is instantly checked by our feeling of security and confidence of its not falling. If this feeling of security did not momently check the feeling of terror, the effect would be terror only, and not sublimity, and we should escape from it as swiftly as possible. So universal is this accompaniment of a feeling of security correcting the feeling of danger in every case of sublimity wherein terror is a constituent, that we are as much justified in asserting that "a feeling of security, either operating openly or latently, is the ruling principle of the sublime," as Burke was in his theory of terror. If terror had been found to be an invariable element of the sublime, the correct statement of the theory would have been—"The sublime is the effect of the concurrence of the two feelings of danger and security." But unfortunately there are many cases in which no feeling of danger can be found to exist. Infinity and eternity are sublime; but although, as he says, "infinity has a tendency to fill the mind with that sort of delightful horror which is the most genuine effect and truest test of the sublime," yet it does not necessarily fill the mind with horror; it may or may not, but in either case it is sublime. Helvetius says, "When God said, 'Let there be light,' and there was light: this image is sublime. But should such an image inspire fear? Yes; because it is necessarily associated in our minds with the idea of the Creator of such a prodigy; and being then seized in an involuntary manner with a dread of the author of light, we feel the sensation of a commencing terror." ('On Man,' vol. ii.) Now we contend that although fear would arise from such a train of thought, yet this train of thought is by no means a *necessary* sequence to the image—"God said, Let there be light, and there was light." It may or may not arise in the mind, but the sublimity produced by the image is not at all dependent upon it.

Lord Kames has a chapter in his 'Elements of Criticism,' on the sublime. He says, "A beautiful object *placed high*, appearing more agreeable than formerly, produces in the spectator a new emotion, termed the emotion of sublimity; and every other emotion *resembling* this emotion of elevation, is called by the same name." He has here the mere etymological notion of sublimity as something elevated, (See Dr. Parr's observations on the derivation of sublime from *supra limum*, in the Appendix to Dugald Stewart's 'Philos. Essays.') That there is little to be learnt from such an inquiry is evident.

Mr. Payne Knight, in his 'Analytical Inquiry into the Principles of Taste,' puts forth the theory that the sublime is the effect of the influence of *mental energy* exciting a sympathetic energy in the mind of the spectator or reader. The objections to this are the same as those to Burke's theory, namely, that it embraces a portion of the truth, which it would substitute for the whole truth. We have only to reflect an instant, and numberless instances of the sublime arise in which no mental energy is implied. Solitude, for example, is certainly sublime; so are infinity, eternity, Mont Blanc, &c. Mental energy is perhaps a more comprehensive formula for sublimity than terror, but it is still incomplete; and if one instance of sublimity can be quoted which does not contain the element asserted to be its 'ruling principle,' it is obvious that the theory must be erroneous.

Dugald Stewart's 'Essay on the Sublime' is entirely philological, and as such alone worthy of attention.

Dr. Thomas Brown combats the notion of a universal sublime, but avoids the real question altogether. All that is positive in his lecture on the subject is that the sublime and beautiful are not two distinct classes of emotions, but the same class, differing only in degree. "It is," says he, "as in the thermometric scale, by adding one portion of caloric after another, we arise at last, after no very long progress, from the cold of freezing to the heat at which water boils; though our feelings at these two points are as different as if they had arisen from causes that had no resemblance; certainly as different as our emotions of sublimity and beauty." ('Lectures on Philos. of Mind,' lvii.) Nothing can well be more erroneous than to take an analogy as a proof. Misled by his analogy, Dr. Brown has falsified the whole nature of the sublime, which, according to him, is but a larger or intenser form of the beautiful, whereas it differs essentially and antagonistically. He takes the instance of a stream gently gliding through fields rich with all the luxuriance of summer, overshadowed at times by the foliage that hangs over it from bank to bank. This is beautiful. He then traces it on to a majestic river, which flows on and deposits itself in the ocean. Here it becomes sublime. And this sublimity he thinks merely the last in the progressive series of emotions, as the boiling-point is the last in the progressive series of ascending heat. "If we were to contemplate this continued progress, we should have a series of emotions which might at each moment be similar to the preceding emotion, but which would become at last so different from our earliest feelings that we should scarcely think of them as feelings of one class." (Ibid.)

The answer to this is, that upon a similar principle of analogical reasoning, you might trace the "progressive series" of feelings which the man underwent from his earliest childhood; and when this series had conducted him to the gallows, you might say that his feelings at that moment were so different from his earliest feelings, that we should scarcely think of them as feelings of one class. Probably not. Nor should we, in our ethical philosophy, class the crimes which brought him to the gallows, with the innocence which commenced the "progressive series" of his emotions.

The whole of Dr. Brown's lecture on this subject is trivial or confused; and because he is unable to analyse the feeling itself, he boldly pronounces it not to be analysed. "It is the vain attempt to define what cannot be defined," he says, "that has led to all the errors and supposed mysteries in the theory of sublimity. Sublimity is not one emotion, but various emotions, that have a certain resemblance—the sublime in itself is nothing; or at least it is only a mere name, indicative of our feeling of the resemblance of certain affections of our mind, excited by objects material or mental, that agree perhaps in no other circumstance, but in that analogous undefinable emotion which they excite." We maintain, on the contrary, that sublimity is *one* emotion, not various similar emotions. It is itself complex, made up of various feelings; but it is one specific feeling, which preserves its characteristic throughout the various shades of difference in the objects which excite it.

Mr. Alison's 'Essays on the Principles of Taste' avoid the real question of sublimity, and the same must be said of his reviewer, Francis Jeffrey, who sums up his theory in these words: "The emotions which we experience from the contemplation of sublimity or beauty are not produced by any physical or intrinsic quality in the objects which we contemplate, but by the recollection or conception of *other* objects which are associated in our imaginations with those before us, and consequently suggested by their appearance, and which are interesting or affecting, on the common and familiar principle of being the natural objects of love, or of pity, or of fear, or veneration, or some other common and lively sensation of the mind." ('Edin. Rev.,' vol. xviii., and 'Essays.')

The first part of this passage is either a truism or an absurdity. A truism, if it be meant to state that as a mere sensation (without any respect to all the sentient being had previously undergone, and which that sensation would necessarily excite) an object in itself is not sublime (a truism however which Mr. Alison asserts to be the conclusion on which his speculations rest: chap. v., sec. 6); an absurdity, if it be meant to state that an object has no intrinsic quality capable of exciting that emotion. The size of a rock, for instance, is the condition of its sublimity; so with the cataract—make it a waterfall, and it ceases to be sublime; yet this difference of size is surely an intrinsic quality in the object which excites the emotion?

The fundamental principle of Mr. Alison's theory is "that all objects are beautiful or sublime which signify or suggest to us some simple emotion of love, pity, terror, or any other social or selfish affection of our nature; and that the beauty or sublimity which we ascribe to them consists entirely in the power they have acquired by association or otherwise, of reminding us of the proper objects of these familiar affections" (Ibid., and Alison's 'Essays,' i.)

This theory is in the highest degree vague. It does not discriminate what constitutes the sublime—it does not analyse that complex emotion, and draw forth its characteristic; and, moreover, in its sweeping generality includes much that it cannot apply to. All objects which excite terror are not beautiful nor sublime; neither are all objects which excite pity beautiful; and so of the rest. To discriminate those which are from those which are not, is impossible on this theory. To resolve the emotion of sublimity into association of ideas, is to say that this special emotion is resolvable into the general law of the human mind, but to avoid an analysis or characteristic statement of this special emotion altogether. It is saying that theft is a crime, and referrible to the general law of criminality, without once demarcating what constitutes theft as a crime, distinguished from murder as a crime. Attraction is the law which regulates the descent of an apple, and association of ideas in like manner is the law which regulates the operation of memory and the flights of imagination; yet as memory and imagination are distinct from the general law, as well as from each other, so also is the emotion of sublimity distinct from the emotion of hatred or beauty. Burke, Knight, Kames, and Price endeavoured to ascertain this distinction. Brown overlooked it, and Alison evades it. Had the special law of sublimity been found, and it was then attempted to be classed in its relation to the general law of the mind, the efforts of Alison and Jeffrey would have been of great importance; but in the meanwhile it was assumed.

It appears to us that the true method of attaining the knowledge of this special law of emotion, is the method of all psychological inquiries, namely, induction. Before attempting to detect the law which regulates it, we must collect all, or a vast number of instances of the sublime, and analysing the elements of each case, endeavour to discover *one* primal element which is invariably a constituent of the emotion, and without which all the other constituents would not be able to form that special emotion of sublimity.

In noticing the theories of former writers we have found their inductions imperfect; they have selected too few instances, and consequently when we came to select others, these theories were subverted by the mere statement of them. It was sufficient to disprove the theory of terror, to quote one instance wherein the terrible had no place, and the same with the theory of mental energy. But these theories, though incomplete, contain much that is true in their analyses.

In proposing a new theory, founded on a wider range of induction, we may observe that if any one instance of the universally acknowledged sublime can be found in which no such element (as the one we assert to be the ruling principle) be detected, then that single instance is a proof of the incompleteness of our theory, and a more extensive induction will be necessary.

It will be necessary for the sake of clearness to make use of purely mental distinctions in treating this subject, though they are liable to be misinterpreted as real distinctions; accordingly we divide the question of the sublime into three: 1. The material sublime—or the sublime of nature. 2. The moral sublime—or the sublime in human actions and ideas. 3. The emotion of sublimity, which these external things excite in us—or that feeling in the mind which gives to certain phenomena of nature, or deeds of man, the attribute of sublimity. Speaking *objectively*, the exciting cause of sublimity is vastness; speaking *subjectively*, the emotion excited is a sense of insignificance.

I. The material sublime. Examine every case of material sublimity, and the most primitive fact will be found to be vastness; whatever feelings may simultaneously concur, this of vastness is invariable. Mere vastness is sublime. Vastness either of form or of power. Hampstead Heath is not sublime, but Mont Blanc is. The Thames is not sublime, but the ocean is. Solitude is sublime—because it is vast, that is, indefinite. But solitude in a room or garden is not sublime. A cataract is sublime, but not a waterfall, yet the one is only larger than the other. Longinus has remarked that the light of a small fire produces no emotion, but that the boiling furnaces of Ætna, pouring out whole rivers of liquid flame, is sublime. Burke remarks that all general privations are sublime because terrible, such as vacuity, darkness, solitude, and silence. But they are sublime because vast, not because terrible; for they are not necessarily terrible, and they are necessarily vast, indefinite.

These instances are sufficient to illustrate the principle. It will be observed that there are some which seem more naturally to derive their sublimity from terror than from vastness, as Ætna for example. But our object was to show that vastness was always a constituent, even when other emotions came into play; and as we have already seen instances where terror does not form one constituent, and that when it does form one, it is still accompanied by vastness, so we prove thereby that vastness is the more general fact. Vastness is sublime as vastness; but terror is not sublime as terror. The difference between a shower and a storm is purely quantitative, yet the storm alone is sublime.

II. The Moral sublime. It is obvious that the moral sublime must differ from the material sublime in proportion as mind and matter differ. Hence vastness, which in the external world is superficial (*in extenso*), in the moral world becomes intense (*in intenso*). Intensity of will equals vastness of form or power. Mere intensity is sufficient to produce the sublime. Œdipus is sublime. Lear, who appeals to the heavens, "for they are old" like him, is sublime, from the very intensity of his sufferings and his passions. Lady Macbeth is sublime from the intensity of her will, which crushes every female feeling for the attainment of her object. Scævola with his hand in the burning coals exhibits an intensity of will which is sublime. It will be difficult to find terror as an element of these cases of the sublime. Mr. Knight's "mental energy" has here more truth; but though a satisfactory explanation of the moral sublime, yet it will not apply to the material sublime. The intensity of power as a source of the moral sublime, has been adopted by Mr. R. Blakey, in his 'History of the Philosophy of Mind,' 1848.

Such appear to us to be the objective qualities of sublimity, but the peculiar emotion they excite has hitherto been thought undefinable: we shall nevertheless attempt it.

III. The emotion of sublimity. As in considering objectively every case of material or moral sublimity, we found as the primary and invariable fact vastness or intensity, so in considering subjectively every case of sublimity as an emotion, we shall find the primary and invariable fact to be a sense of our own insignificance; of our inferiority to the object, or to the will which prompted the deed; and this sense of inferiority has guided mankind in the employment of a word expressing elevation for sublimity. Mere vastness excites this emotion by exciting a corresponding sense of our smallness. Mere intensity excites this emotion by exciting a corresponding sense of our feebleness. Vary the objects—vary the emotions as you may, there will invariably be this one feeling of comparative insignificance. Take as an example the sublime words of Scripture, "I am the High and the Lofty One, who inhabiteth eternity." Nothing can exceed the grandeur of that idea, and he who conceives it conceives also, at the same time, the corresponding idea of his own small and finite nature. In the violent dashing of a cataract, in the roar of the ocean, in the violence of the storm, or in the majestic quiet of Mont Blanc preserving its calm amidst all the storms that play around it, or in the concentrated will of a Scævola, Horace, Brutus, or Œdipus, in all these cases we are moved by a vivid feeling of some greater power than our own, or some will more capable of suffering, more vast in its strength than our feeble vacillating will. It is from this reason that an imaginative mind experiences more emotions of sublimity than another. In proportion as we comprehend the majesty of nature, or the amount of self-sacrifice in an heroic action, we comprehend our own inferiority to them.

In conclusion we may thus sum up our theory. The invariable condition of sublimity in objects, either material or moral, is vastness or intensity. The invariable condition of the emotion of sublimity—that which distinguishes this emotion from every other emotion—is a comprehension of this vastness with a simultaneous feeling of our own comparative insignificance, together with a concomitant sense of present security from any danger which might result from this superior power. The antithesis to the emotion of sublimity is the emotion of contempt.

SUBMARINE DESCENT. [DIVING BELL.]

SUB-MULTIPLE. [ALIQUOT PART.]

SUBORNATION OF PERJURY. [PERJURY.]

SUBPŒNA. [WITNESS.]

SUBPŒNA, WRIT OF, IN PLEADING. [PLEADING IN EQUITY.]

SUBSALTS. [SALTS; CHEMICAL NOMENCLATURE, *Nomenclatu Salts.*]

SUBSIDIARY. A quantity or symbol is so called whe is not essentially a part of a problem, but is introduced to help in e solution. The term is particularly applied to angles, since the gonometrical tables give a great power over their management, ich causes their frequent introduction, even in problems in whic here is no question of angular quantity. For example, suppose it required to calculate $ax+b\sqrt{(1-x^2)}$, where $a = {\cdot}29164$, $b = 3{\cdot}0$ 8, $x = {\cdot}11316$. Assume

$x = \cos\theta$, $a = r\cos\phi$, $b = r\sin\phi$, which gives θ from the tables, and ϕ and r from the tables and from

$$\tan\phi = \frac{b}{a},\ r = \frac{a}{\cos\phi}.$$

The quantity to be calculated is

$$r\cos\phi\cos\theta + r\sin\phi\sin\theta, \text{ or } r\cos(\phi-\theta),$$

$$\text{or} \qquad \frac{a\cos(\phi-\theta)}{\cos\phi},$$

and the final result is found from the tables in much less time than $ax + b\sqrt{(1-x^2)}$ could be calculated by ordinary means. There is, of course, no rule for the most convenient introduction of subsidiary angles: every case must be treated according to the circumstances it presents.

SUBSIDY, from *subsidium*, a Latin word signifying aid or assistance. "Subsidies," says Lord Coke, "were anciently called auxilia, aides, granted by act of parliament upon need and necessity; as also for that originally and principally they were granted for the defence of the realm and the safe keeping of the seas," &c. The word used in its general sense was applied to aids of every description; these were of two kinds, one perpetual, the other temporary. Those which were perpetual were the ancient or grand customs, the new or petty customs, and the custom on broad-cloth. The temporary included tonnage and poundage; a rate of four shillings in the pound on lands, and two shillings and eightpence on goods, aliens paying double; and the fifteenths or tenths, &c., of moveable goods. The limited sense, which is also the more common sense, of the word subsidy, attaches only to the rate on lands and goods.

The grand customs were duties paid on the exportation of wool, sheepskins, and leather, at the rate of, for every sack of wool weighing thirty-six stone, half a mark, or six shillings and eightpence; for every three hundred sheepskins, half a mark; for a last of leather, a mark, or thirteen shillings and fourpence. The petty customs were payable by merchant strangers only, and consisted of an excess of one half over and above the grand customs payable by native merchants. The custom on broadcloth was first given to the king in the 21st year of Edw. III., to indemnify him for the loss he incurred in consequence of the practice, then beginning to prevail, of making up the wool into cloth in this country previous to its exportation. There were also two species of customs payable on wines: one called butlerage, payable by foreigners importing wines, at the rate of two shillings for every tun of wine; the other, called prisage, payable by natives at the rate of, for every vessel importing ten tuns of wine, one tun; for every vessel importing twenty or upwards, two tuns; taken one tun from before, the other from behind the mast. This was compounded for by the payment of 20*s.* for each tun to which the king was entitled.

The origin of these customs seems uncertain; Lord Coke is very anxious to prove that they were in the first instance established by the common consent of the realm in parliament assembled. In support of this he cites Philip de Comines, lib. v., fo. 233. Before and during Lord Coke's time, as well as immediately after it, the origin and nature of this kind of subsidy were most fully and ably discussed. Besides what may be called the private property of the crown, the king had a right to require contributions from the inhabitants of particular districts towards the expense of repairing bridges and the walls of towns, which contributions were called pontage and murage; and to grant by charter to any city the right to levy tolls upon all vendible things coming into the town. There were also other sources of revenue, the temporalities of vacant bishoprics, the forfeitures arising from felonies, &c. In the earlier periods these seem to have been considered sufficient to maintain the royal state, the courts of justice, &c., and also the ordinary expenses of any wars in which the king might be engaged. In the sixth year of Richard II., the commons petitioned the king that he would live upon his own revenues, and that wards, marriages, releases, escheats, forfeitures, and other profits of the crown might be kept to be spent upon the wars for the defence of the kingdom. In addition however to these duties of defending the kingdom by foreign wars, the king was bound to protect the merchants at sea from pirates, &c., and for this purpose a practice prevailed twice in the year "to scour the narrow seas." To defray the expenses of the royal navy, the king collected at the ports of his kingdom certain sums upon all merchandise imported or exported. These sums were called customs, a word which in itself indicates the earliness and uncertainty of their origin. In process of time however, the ordinary sources of the king's revenue being continually diminished by the alienation of crown lands, &c., while the expenses of the crown were increased, the kings imposed of
[illegible] own authority such sums as varied from the original amount
car[illegible]d, and were complained of as unreasonable by the people. The
against [illegible]liamentary history is full of remonstrances and petitions
There was [illegible]ous and unaccustomed impositions, maltolts (evil tolls), &c.
might pay [illegible]stance also of a petition by the merchants that they
Ultimately the [illegible] but be allowed to protect their ships themselves.
of the collection of [illegible] were driven by their necessities, the difficulties
position, to have recou[illegible]gular duties, and the circumstances of their
to be collected as customs [illegible] to parliament to fix and authorise the sums
[illegible] The first statute on the subject occurs in the third year of the reign of Edward I., when the ancient or grand customs were fixed at the sums already stated.

It is observable that in no instance was the right of the king to collect some duties disputed; all that is complained of is the excess and unreasonableness of the sum recently imposed. Many statutes occur on the subject, but their provisions were frequently violated, down to the reigns of Elizabeth and the Stuarts. In these later times, however, such infringements were not passed over lightly. In the reign of James I. the question as to the right of the king to increase the customs upon merchandise, without assent of parliament, was raised on the occasion of his imposing 5*s.* per cwt. on currants. The court of exchequer decided that the king had such right, on the grounds, 1st, that his extraordinary and absolute prerogative was not bound by the statutes restraining him from increasing the customs without assent in parliament; 2nd, because the extra duty "was not a burden to the commonwealth, but to delicate mouths." This decision however raised great discussion in parliament, who pronounced it to be illegal. The writs for ship-money in the time of Charles I. created a similar ferment, and notwithstanding the petition of rights, the question cannot be said to have been entirely set at rest till up to the period of the Revolution.

The petty customs were originally founded on a bargain between the foreign merchants and king Edward I., by which they agreed to pay him the amount of them, in consideration of certain privileges granted them, and a release to them of all other prises and takings. Butlerage has the same origin, but is perhaps of an earlier date. Prisage is stated by Lord Coke himself to be due to the king by prescription, and the right of the king to it seems to have stood upon that alone; that right must have been one of inheritance, since by royal charters it was granted to the city of London and to the Cinque Ports for ever.

Tunnage and poundage was a duty varying in amount at different times from 1*s.* 6*d.* to 3*s.* upon every tun of wine, and from 6*d.* to a 1*s.* upon every pound sterling of merchandise coming into the kingdom. The object in granting it was said to be, that the king might have money ready in case of a sudden occasion demanding it for the defence of the realm or the guarding of the sea. In the course of the argument in the case of ship-money in 13 Charles I., the king's duties are said to amount to 300,000*l.* This probably was the aggregate of the customs and tunnage and prisage.

The taxes called tenths and fifteenths were the tenth or fifteenth part of the value of moveable goods. Other portions, such as the fifth, eighth, eleventh part, were sometimes, but rarely, also levied. These taxes seem to have had a parliamentary origin. Henry III. received a fifteenth in return for granting Magna Charta and the Charta de Foresta. In the earlier periods never more than one subsidy and two fifteenths were granted. About the time of the expectation of the Armada (31 Eliz.), a double subsidy and four fifteenths were granted. Subsidies and fifteenths were originally assessed upon each individual, but subsequently to the 8 Edward III., when a taxation was made upon all the towns, cities, and boroughs, by commissioners, the fifteenth became a sum certain, being the fifteenth part of their then existing value. After the fifteenth was granted by parliament, the inhabitants rated themselves. The subsidy, never having been thus fixed, continued uncertain, and was levied upon each person in respect of his lands and goods. But it appears that a person paid only in the county in which he lived, even though he possessed property in other counties. Certain it is that the subsidy continually decreased in amount. In the eighth year of the reign of Elizabeth it amounted to 120,000*l.*, in the 40th to 78,000*l.* only. Lord Coke estimates a subsidy (probably in the reign of James I. or Charles I.) at 70,000*l.*; the subsidy raised by the clergy, which was distinct from that of the laity, at 20,000*l.*; a fifteenth at about 29,000*l.* Eventually the subsidy was abolished, and a land tax substituted for it.

SUBSTANCE. In general usage substance means a solid. In philosophical speculations it has undergone the fate of most general terms, and has been tortured into all possible shades of meaning. In physical speculations it has usually been taken as an equivalent to matter; but in metaphysical speculations its meaning, as sanctioned by the highest authorities, has remained true to its etymon (*sub-stans*, that which *stands under* phenomena). This meaning will be rendered intelligible by the notion of some Hindu philosophers, who supposed the world to rest on the back of an elephant, and that the elephant stood on the back of a tortoise; what supported the tortoise, they omitted to explain. In adopting their theory, we may add that *that* which the tortoise stood upon was substance.

As we know that all phenomena must depend upon noumena, of which they are only the manifestation; or, to use the language of the schoolmen, as all accidents must be accidents of *something*, and must depend on that something for their existence, so in pushing our analysis to its limit, we must finally arrive at a point to which we can give no antecedent, which we are forced to assume as final, and as standing under or supporting the whole, and this we call substance. It is the fundamental fact of all existence. We can never know it, for we only know phenomena, which are its appearances. We can never conceive it, for the first attempt to conceive it brings it within the sphere of our ideas, which are only those of phenomena. We can never imagine it; but we are compelled to assume it. It is to us a logical fact, not a noumenal one. Necessary as the basis of all speculation, as the "point" in mathematics, but, like the point, for ever a mere logical distinction. It is needful for all men to know that this substance is, with respect to the mind, a merely logical distinction from its attributes; and it is needful also to know that as the mind can never transcend the sphere of its action, and consequently never know more than the attributes, all that it can predicate of substance must be false, for substance is to it a mere negation; if it would affirm anything of substance, it must inevitably affirm it by its attributes, which it alone can know positively.

It is from inattention to this latter fact that metaphysicians have blundered and misunderstood each other so constantly. You cannot conceive a point which has neither length nor breadth; you must assume it. You cannot conceive substance shorn of its attributes, because those attributes are the sole staple of your conceptions; but you must assume it. Analyse as you will, you can never get beyond a vague and negative conception of a certain substratum, which, whenever you attempt to realise it, you must invest with attributes. Glass is a substance, at least is called so in common language. Analyse it, and you will find that it is no substance—that it is merely the co-existence of flint and alkali. Your substance then has vanished with the analysis. It was found to be flint *and* alkali, nothing more; no distinct element, no *substratum* was discovered. Where then was your glass substance? The glass was a mere mode of existence of two particles of flint and alkali; it was in itself nothing, it had no existence apart from those particles, it had no *substratum*. Analyse the flint in the same way, and you will find the flint to be in itself no substance, but a mode of existence of some other particles. And yet the mind refuses to admit that this analysis could be so continued ad infinitum, thus reducing everything to mere phenomena; it is impelled to stop somewhere, and to ask, "attributes of what?" and there where it stops it recognises substance. Hence Spinoza's definition of substance being existence itself.

Fichte, the most scientific expositor of idealism, has denied all substance except that of the Ego, and he says, "Attributes synthetically united give substance, and substance analysed gives but attributes; a continued substratum, a supporter of attributes is an impossible conception." ('Wissenschaftslehre.') Granted an impossible conception, but not therefore an impossible fact. Fichte assumes that the subjective conception—the idea—is the complete correlation and adequate comprehension of the whole objective fact; and if this point be admitted, his system is irrefutable, for attributes being obviously mental conditions, and as beyond them we are conscious of nothing, so nothing but what they affirm can exist. Interrogate consciousness, and you will get no answer that will apply to a substance. It knows only attributes.

If we dissent from these conclusions, and maintain that there is substance apart from its attributes (though we insist on this distinction being purely logical), it is because the idealists have not proved the fundamental position on which all such speculations rest, namely, the truth of the correlation between the conception and the object, so that the one should be taken as the entire expression of the other.

In our analysis of substance it is impossible to get beyond attributes; and therefore, subjectively speaking, substance is nothing more than the synthesis of attributes: but does this entitle us to assume that it is equally the case objectively? Not until the subject has been proved to be the complete expression of the object.

But the truth is, attributes themselves are but the conditions excited in us by objects. The Ego acted on by the non-Ego undergoes certain affections: these mental affections are variously extension, colour, weight, hardness, &c., and these are all the effects of the action of the non-Ego upon the Ego, and as a consequence these are all we know, and all we know of the non-Ego. To call substance therefore the synthesis of attributes, is to say that in the synthesis of our mental affections is contained all that *constitutes* the non-Ego, instead of saying that in the synthesis of our mental affections is contained all we can positively *know* of the non-Ego; it is saying that we include all existence, and that beyond our conceptions nothing exists; it is taking the human mind as the measure of the universe.

We maintain therefore, that inasmuch as what we call attributes are not vague abstractions, but positive effects of matter acting on the sensory (and we assume the existence of matter because Idealism has failed in disproving it); so there must be substance or cause to produce those effects; and although we can only know these effects and *by* these effects, yet we are necessitated to assume an inconceivable cause or substance. We do not know this substance: we only know what sensations it excites in us.

The stronghold of Idealism is consciousness. In consciousness there is nothing but transformations of itself—no substance, no external world is given; it knows, it feels, it is conscious of nothing but itself. But consciousness is equally the stronghold of realism; for we are as conscious that what we call substance, or the world, is not ourselves, and does not depend upon us, and is a distinct existence, as we are of our own existence. Hence the universality of the belief of an external world—hence the impossibility of the idealists' conceiving for an instant the non-existence of substance.

In conclusion we may observe, that substance is the unknown, unknowable substratum on which rests all that we experience of the external world; it is the hidden noumenon whose manifestations as represented in perception we call matter and the phenomena of matter, and of which every positive predicate must necessarily be false, and consequently all inquiry into its nature baseless.

SUBSTITUTION. One of the most important methods of forming chemical substances, and of ascertaining the constitution of compounds, is that known as substitution. The term substitution, as thus chemically applied, simply means the replacement of a body already in combination by another body not in combination, and of course includes all processes of single or double decomposition. Thus, in a compound A B, substitution of B for C may be effected by simply bringing C into contact with A B, the new compound A C being produced: this case of substitution is one very frequently performed in chemical research and manufacture, and is known as single decomposition or single elective affinity. Again, in a compound A B, substitution of B by C may be effected by bringing a compound C D, containing C, into contact with A B, thus producing the required substance A C; this method of substitution is fully as important as the other just mentioned, and is known as double decomposition or double elective affinity, because there are, so to speak, two elections or choices going on, namely, A for C, and B for D, whereas in the former illustration only one occurs. By using varying amounts of a substituting body, C_x, and bringing forces other than the chemical to his aid, the chemist can sometimes produce several distinct compounds of the same bodies, thus :—$AB_x + C_2 = AB_{x-2}C_2 + B_2$ or $AB_5 + C_5 = AC_5 + B_5$. Frequently the body substituted unites with one half of the substituting body, thus :—$AB + C_2 = AC + BC$.

Although, strictly speaking, single and double decomposition are processes of substitution, it is found convenient to restrict the term substitution to cases in which organic compounds are being operated on, while the phrases single decomposition and double decomposition are conventionally applied to inorganic transformations only. [CHEMICAL AFFINITY.]

The simplest examples of substitution occur when chlorine, or either of its analogues, bromine and iodine, is made to act upon an organic compound. Thus chloride of ethyl (C_4H_5, Cl), by the action of chlorine suffers replacement of its hydrogen by chlorine; hydrochloric acid being formed and the following bodies successively produced :—

Chloride of chlorethyl	. . . . .	$C_4\left\{\begin{matrix}H_4\\Cl\end{matrix}\right\}Cl$
" bichlor-ethyl	. . . . .	$C_4\left\{\begin{matrix}H_3\\Cl_2\end{matrix}\right\}Cl$
" trichlor-ethyl	. . . .	$C_4\left\{\begin{matrix}H_2\\Cl_3\end{matrix}\right\}Cl$
" quadrichlor-ethyl	. . . .	$C_4\left\{\begin{matrix}H\\Cl_4\end{matrix}\right\}Cl$
" perchlor-ethyl or sesquichloride of carbon	. . . .	C_4Cl_5Cl

The constitution or construction of the original compound from which such a series of derivatives is obtained seems to alter but little. As might be expected from the nature of the elements, the boiling point of a body containing chlorine in the place of hydrogen is higher in direct proportion to the amount of hydrogen replaced. Specific gravity also undergoes relative increase; while vapour volume remains constant. Only when complete substitution of one body by another has taken place does the molecular arrangement of the original compound appear to give way.

The substitution of chlorine for oxygen, and of oxygen by hydrogen, is frequently performed by chemists. Peroxide of nitrogen (NO_4), also, may be introduced into organic compounds by acting upon them, under certain conditions, with nitric acid; in these cases hydrogen is displaced and forms water with the fifth equivalent of oxygen, while peroxide of nitrogen takes the place of the hydrogen.

SUBSTITUTION, a very common algebraical process, being, as its name imports, the substituting for any quantity another which is equal to it.

A method of approximation, which is frequently used and of great importance, has obtained the name of *successive substitution*. Let any equation be reduced to the form

$$x = a + e\phi x,$$

where e is less than unity, and ϕx a function of x. If we make $x = a$, the error thereby committed is less than ϕx, being $e\phi x$, in which e is less than unity. Take this value $x = a$, and substitute it on the second side, giving $x = a + e\phi a$: this value is nearer than the last in most cases, for it should be

$$\begin{aligned} x &= a + e\phi\,(a + e\phi x) \\ &= a + e\phi a + e^2\phi' a.\ \phi x \text{ nearly,} \end{aligned}$$

where $\phi' a$ is the differential coefficient of ϕa. The last error was $e\phi x$, and the present error is less, if $e\phi' a$ be less than unity. Generally, if for x we write $a+p$, and if p be erroneous by a quantity of the order e^n, we shall have, by one more substitution,

$$x = a + e\phi(a+p).$$

Now the error of $\phi(a+p)$ will be of the order e^n, and that of $e\phi(a+p)$ of the order e^{n+1}. There is then a continual approximation to the value of x.

Beginning with $x = a + e\phi a$, in which the error is of the order e^2, we have

$$x = a + e\phi(a + e\phi a),$$

in which the error is of the third order. Rejecting terms of the third order, we have

$$x = a + e\phi a + e^2\phi a\phi' a.$$

Substitute this again, and we have

$$x = a + e\phi\left\{a + e\phi a + e^2\phi a\phi' a\right\},$$

in which the error is of the fourth order. Rejecting terms of the fourth order,

$$x = a + e\phi a + e^2\phi a\phi' a + e^3\left\{ (\phi' a)^2\phi a + \frac{\phi'' a}{2}(\phi a)^2 \right\}$$

and so on: the development being made by TAYLOR'S THEOREM. This would lead in effect to the celebrated theorem of Lagrange; but the actual method of substitution is sometimes preferable.

SUBTANGENT, SUBNORMAL. [TANGENT.]

SUBTENSE, means any line, angle, &c., opposite to or *subtending* a line or angle spoken of. Thus the chord of a circle is the subtense of the arc and of the angle at the centre. The term is now not much used.

SUBTRACTION, SUBTRAHEND, MINUEND. The process of subtraction is the removal of a part equal to the less from the greater. The quantity to be diminished (*minuendum*) was called the *minuend;* the quantity to be withdrawn (*subtrahendum*), the *subtrahend;* and the remaining part, the *remainder*. The terms subtrahend and minuend are almost out of use, though often very convenient.

The operation of subtraction is often described in a way which might be practised, but is not; and the explanation of the possible mode applied to the actual mode makes confusion. It is obvious enough that if parts of A be subtracted severally from greater parts of B, the remainders put together make up the whole remainder. Thus, 24 can easily be taken from 76, for 7 tens exceeds 2 tens by 5 tens, and 6 exceeds 4 by 2, so that 52 is the remainder required. But when we come to take 48 from 93, the preceding mode of partition is useless. To remedy this, it is proposed in the explanation to *borrow* 1 of the 9 tens in 94, and to put it on to the 4: then 8 from 18 leaves 5. Now take the 4 tens of 48, and subtract from the *remaining* 8 tens of 93, and 4 tens are left: the answer then is 45. The process would be as follows:—

93	8 from 3, impossible; borrow a ten from 90; 8 from 13 leaves
48	5. Take 4 tens from the remaining 8 tens, one of the 9
—	tens having been borrowed, and 4 tens remain.
45	

This process is actually used on the Continent; but with us, as all the world knows, there is a different process, as follows:—

93	8 from 3 impossible: take 8 from 13, and 5 remains. *Carry**
48	one to 4, giving 5, and subtract 5 tens from 9 tens, giving 4
—	tens.
45	

There is quite a different principle in this process, which is as follows:—If two numbers be equally increased or equally diminished, the difference remains the same. Having arbitrarily increased the 3 in the upper line by 10, the lower line must be somewhere or other increased by 10, in order to keep the difference (which is all that is wanted) unaltered.

The object in view is attained by increasing the upper line by ten *units*, and the lower line by one *ten*.

For further detail, see COMPUTATION.

SUCCESSION. This is a legal term derived from the Roman "Successio," which signifies a coming into the place of another, and Successor is he who comes into such place.

The Roman term signifies a coming into the place of another so as to have the same rights and obligations with respect to property which that other had. There might be successio either by coming into the place of a person living, or by becoming the successor of one who was dead. Gaius (iii. 77, &c.) gives instances of successio in the case of persons living, one instance of which is the Bonorum Cessio according to the Lex Julia. Succession was again either Universal or Singular. The instances of universal succession (per universitatem) which Gaius (ii. 97) enumerates, are the being made a person's heres, getting the possessio of the bona of another, buying all a man's property, adopting a person by adrogatio, and admitting a woman into the manus as a wife; in all of which cases all the property of the several persons enumerated passed at once to the person who was made heres, or got the bonorum possessio, or bought the whole property, or adopted another by adrogation, or married the woman. An instance of singular succession is the taking of a legacy under a man's will.

The term Succession is used in our language. We speak of the succession to the crown or the regal dignity, and the term implies that the successor in all things represents the predecessor. Indeed, the king, as a political person, never dies, and upon the natural death of a king the heir immediately succeeds. The English heir-at-law takes the descendible lands of his ancestor as universal successor; and the executor takes the chattels real and other personal property of his testator as universal successor. The general assignee or assignees of a bankrupt or insolvent take by universal succession.

Blackstone says that "corporations aggregate consist of many persons united together into one society, and are kept up by a perpetual succession of members, so as to continue for ever." It is true that when members of a corporate body die, others are appointed to fill up their places, but they do not succeed to the others in the Roman sense of succession—they simply become members of the corporation. But it has been established in some cases that the use of the word "successors" implies that the legislature meant to establish a corporation; and yet it is certain that a feoffment of land to a corporation aggregate without the word "successors" is a valid grant. In a feoffment to a corporation sole the word "successors" is necessary. The succession in the case of a corporation sole follows the nature of the Roman succession. In the case of a corporation aggregate there is no succession, and the rule that a corporation may be established by the use of the word "successors" in a statute is founded on an erroneous understanding of the term "successors."

SUCCESSION DUTIES. For many years persons succeeding to personal property (including leaseholds) whether they took by will as executors or legatees, or merely as administrators or next of kin, were charged with *Legacy Duties*, which were payable over and above the stamp duty, then and still levied in the first instance, on the grant of probate or letters of administration, according to the estimated sworn value of the personal property of the deceased. The legacy duty was chargeable after the estate of the deceased had been realised and administered, on the property distributed among the legatees or next of kin, as the case might be; and varied in amount, according to the consanguinity of the next of kin, or the absence of any relationship between the legatee and the testator. The exemption of real estate from this species of taxation long complained of as creating an undue preference in favour of the holders of landed property, has at last been removed. By the Succession Duties Act, 1853, duties are imposed on every succession to property, whether real or personal, according to the value and the relationship of the parties to the predecessor. Where the successor is the lineal issue or lineal ancestor of the predecessor, 1*l*. per cent.; where a brother or sister, or a descendant of a brother or sister, 3*l*. per cent.; where a brother or sister of the father or mother, or a descendant of the brother or sister of the father or mother of the predecessor, 5*l*. per cent.; where a brother or sister of the grandfather or grandmother, or a descendant of the brother or sister of the grandfather or grandmother of the predecessor, 6*l*. per cent.; and where the successor is in any other degree of collateral consanguinity to the predecessor, or is a stranger in blood to him, 10*l*. per cent. The value of the succession, if it be to real property, is ascertained by considering the interest of the successor as of the value of an annuity equal to the annual value of the property, estimated as the act directs; and the duty may be paid by eight equal half-yearly instalments, or at once, according to the wish of the party liable thereto.

SUCCINANILE. [SUCCINIC GROUP.]

SUCCINIC ACID. [SUCCINIC GROUP.]

SUCCINIC ETHER. [ETHYL.]

SUCCINIC GROUP. The generic name of succinic acid and its derivatives.

Succinic acid ($2HO, C_8H_4O_6$) exists naturally in AMBER (*succinum*), from which resin it was first obtained as one of the products of destructive distillation. In combination with potash it also occurs in the milky juice of the leaves and stems of wormwood (*Artemisia absinthium*). It may be artificially prepared from stearic acid or other fatty matter by oxidation with nitric acid; in this reaction, pimelic and adipic acids are also formed, as well as a body that was at first thought to be a distinct acid (*lipic acid*), but which has since been shown to be identical with succinic acid. The most advantageous method of forming succinic acid is that known as Dessaigne's, and consists in fermenting crude malate of lime with eight or nine per cent. of decayed cheese and three times its weight of water. The mixture must be kept at a temperature of 100° Fahr. for about a week, when the malate will be found to be changed to a crystalline sediment of succinate and carbonate of lime, acetate of lime remaining in solution. The precipitate decomposed by boiling dilute sulphuric acid, and the solution evaporated and treated with animal charcoal furnishes the acid in rhombic prisms or tables.

---

* The student may well ask *from where!* The term "carry" is not the proper one.

Succinic acid is inodorous and colourless, has an acid taste, and is very stable. It is very soluble in hot water, moderately so in cold water or alcohol, and only slightly soluble in ether. When heated it fuses at a temperature somewhere about 450° Fahr.; and above that point sublimes and condenses in a beautifully white crystalline mass of *succinic anhydride* ($C_8H_4O_6$); complete dehydration can, however, only be effected when the succinic acid has been previously mixed with phosphoric anhydride. Succinic acid is not acted on by nitric acid, chromic acid, chlorine, or even a mixture of hydrochloric acid and chlorate of potash. Heated with caustic potash it yields oxalate of the base and a carburetted hydrogen; and furnishes acetic acid by distillation with peroxide of manganese and acetic acid.

Succinates are, for the most part, either neutral salts ($2\,MO, C_8H_4O_6$) or acid salts ($MO, HO, C_8H_4O_6$). They are tolerably stable, and are characterised by giving a red-brown precipitate with persalts of iron.

Neutral succinate of potash contains ($2\,KO, C_8H_4O_6 + 4$ Aq.); *acid succinate of potash* ($KO, HO, C_8H_4O_6 + 4$ Aq.) The latter is the salt contained in wormwood; it crystallises in regular six-sided prisms, and is prepared by saturating a given quantity of succinic acid with carbonate of potash, and then adding a second quantity of the acid. *Succinate of ammonia* ($2\,NH_4O, C_8H_4O_6$) is sometimes employed to separate iron from nickel, cobalt, and manganese; the solutions must be perfectly neutral. *Succinate of soda* has been electrolysed by Kolbe; carbonic acid and oxide of methyl are evolved at the positive pole. Double *succinate of magnesia and potash* contains ($KO, MgO, C_8H_4O_6 +$ 5 Aq.).

Succinate of ethyl (succinic ether) ($2\,C_4H_5O, C_8H_4O_6$) is a liquid of specific gravity, 1·036; boiling point, 417·2° Fahr.; it is obtained on distilling succinic acid with alcohol and sulphuric acid; chlorine converts it into white acicular crystals of *perchlorosuccinate of perchlorethyl* (chlorosuccinic ether), ($2\,C_4Cl_5O, C_8Cl_4O_6$). The last-named body, by distillation, yields *chlorosuccide* ($C_6Cl_4O_2$); and by action of alkalies gives a salt containing *chlorosuccic acid* ($C_6HCl_3O_4$?).

Sulphosuccinic acid ($3\,HO, C_8H_3O_5, 2\,SO_3 + 2$ Aq.) is produced when anhydrous sulphuric acid and succinic acid are brought into contact. When pure it occurs in granular crystals, very soluble in water, alcohol, or ether; it is deliquescent, and requires three equivalents of base to saturate it.

Succinic oxychloride, or *chloride of succinyl* ($C_8H_4O_4Cl_2$), is a colourless highly refracting oil, obtained on distilling equivalent quantities of succinic anhydride and oxychloride of phosphorus. It fumes strongly, has a suffocating odour, boils at about 374° Fahr., and has a specific gravity of 1·39.

Succinyl ($C_8H_4O_4$)″ may be assumed to exist not only in the above compound, but also in all the other members of this group. If it exists it is diatomic, and plays the part of two equivalents of hydrogen.

Succinic amides are three in number. 1. *Succinamide* $\left(C_8H_8N_2O_4 = N_2\left\{\begin{array}{c} C_8H_4O_4'' \\ H_2 \\ H_2 \end{array}\right.\right)$. This substance is slowly formed, in colourless crystalline grains, on exposing a mixture of succinate of ethyl with twice its volume of strong solution of ammonia. It is insoluble in alcohol or ether, and almost insoluble in cold water; boiling water readily dissolves it, and the solution does not precipitate metallic salts. *Succinanilide*, or *diphenylsuccindiamide* $\left(C_{32}H_{16}N_2O_4 = N_2\left\{\begin{array}{c} C_8H_4O_4'' \\ (C_{12}H_5)_2 \\ H_2 \end{array}\right.\right)$ is the insoluble product of the action of succinic acid upon aniline. 2. *Succinamic acid* ($C_8H_7NO_6$) seems to have been obtained as a silver salt, but has not yet been isolated. *Succinanilic acid*, or *phenylsuccinamic acid*, contains $\left(C_{20}H_{11}NO_6 = N\left\{\begin{array}{c} C_8H_4O_4'' \\ C_{12}H_6 \end{array}\right., HO\right)$. 3. *Succinimide*, or *bisuccinimide* ($C_8H_5NO_4 + 2$ Aq.), is a product of the transformation of succinamide by heat. It crystallises in beautiful rhombic tables, is very soluble in water, less so in alcohol, and slightly so in ether. It melts at 410° Fahr. It is isomeric with succinamic acid, but does not combine with potash. *Chlorosuccinimide*, or *chlorozosuccic acid* ($C_8HCl_4NO_4$), results from the action of ammonia on chlorosuccinic ether. It may be easily separated from other bodies that are simultaneously formed, and then occurs in prisms; it is volatile, soluble in alcohol or ether, and decomposes carbonates with effervescence. *Succinanile* or *phenylsuccinimide* ($C_8H_4(C_{12}H_5)NO_4$), is that part of the product of the action of succinic acid upon aniline that is soluble in hot water. Purified by recrystallisation from alcohol, it forms beautiful colourless needles, insoluble in cold water, and volatile without decomposition.

SUCCINIMIDE. [SUCCINIC GROUP.]

SUCCINUM is a bituminous substance of a peculiar kind, the natural history of which has been already detailed. [AMBER, in NAT. HIST. DIV.] It is not now used in the crude state in medicine, but is employed to yield the oleum succini, or oil of amber. This is procured by the destructive distillation of amber, which is put into a glass, copper, or iron retort, fitted with a glass alembic properly luted. A gentle heat is applied by means of a sand-bath, by which the amber is melted, and a little volatile oil passes over; after this the amber swells greatly, and the distillation proceeds rapidly. By this process three very distinct products are obtained, namely, impure succinic acid, which adheres to the neck of the retort; an acid liquid (called spiritus volatilis succini), in which succinic and acetic acids exist mingled with empyreumatic oil; and, lastly, the volatile oil of amber, which is to be separated from the acid liquid by careful pouring off. What remains in the retort is *colophony* of amber, which is used to make varnish. The volatile oil thus obtained is impure, containing various pyrogenous ingredients, and requires repeated distillations to purify it. If in the third or fourth of these the process be interrupted when about two-thirds only of the oil has passed into the receiver, there is obtained a volatile oil of a light yellow colour, a peculiar bituminous odour, and of the specific gravity 0·880. If the distillation be continued too long, an empyreumatic oil is evolved, which gives to the other a coffee-brown hue; and this is the general appearance of rectified oil of amber. By some writers freshly prepared charcoal is directed to be put into the retort when the impure oil is to be distilled, but that is very improper, as by its means the pyrogenous principles, which it is the object of the rectification to separate, are very abundantly generated. The purest oil has a sharp burning taste, an acid re-action, and on exposure to the air becomes brown and inspissated. Various resinous matters substituted for amber may all be detected by the absence of succinic acid.

Volatile oil of amber probably contains a large portion of creasote, as may be inferred from the analogous action of nitric acid on it and on creasote. One part of rectified oil of amber, and three parts of moderately strong nitric acid, form a magma, which has the odour of musk, and is called *artificial musk*. Rectified oil of amber is stimulating, anti-spasmodic, and rubefacient. It is now little given internally, except in combination with ammonia, in the celebrated *eau-de-luce*, for which the *tinctura ammoniæ composita* of the Pharmacopœia was a substitute, but now omitted. This is to be applied to the nostrils in fainting, hysteria, and epilepsy, or a very few drops diluted with water may be taken internally. Oil of amber is beneficially rubbed along the spine in the later stages of hooping-cough. One ounce of rectified oil of amber, with half an ounce of tincture of opium, forms a good embrocation in tic-doloureux; its disagreeable odour is an obstacle to its employment when the face is the seat of the disease; but it proves a most valuable application when the limbs begin to lose their tone and swell in advanced life. It is extremely efficacious against the cramps of the limbs in Asiatic cholera, but which may be prevented by pressing the foot against a board or other firm body at the foot of the bed, when the patient feels cramp coming on.

SUCCINYL. [SUCCINIC GROUP.]

SUCCISTERENE. A white crystalline matter formed during the distillation of amber.

SUCROSE. [SUGAR.]

SUDORIC ACID ($C_{10}H_9NO_{14}$), *Hydrotic Acid.* In addition to lactic acid, there is contained in human perspiration the soda salt of another acid to which the above names have been given. Sudoric acid and its salts are uncrystallisable. The sudorate of silver has the formula $C_{10}H_8AgNO_{14}$. This salt is insoluble in alcohol; with this exception all the salts of sudoric acid are soluble in alcohol.

SUET is a variety of the fatty or adipose tissue of animals, accumulated in considerable quantity about the kidneys and the omentum, or caul, of several of the domestic quadrupeds. There are several kinds of it, according to the species of animal from which it is procured, such as that of the hart, the goat, the ox, and the sheep (ovis aries). This last, which is whiter than beef-suet is officinal. It belongs to the class of saponifiable fats. In the recent state it is white, easily broken, being solid at the ordinary temperature of the air, subdiaphanous, scarcely possessed of odour, or only of a slight peculiar one, due to the hircine, which in the process of saponification evolves a volatile strong-smelling acid (hircinic acid of Chevreul), but possessing a very disagreeable one when putrifying. It readily spoils on exposure to the air, becoming rancid and yellow, but may be restored again to whiteness by chloride of lime or chloride of magnesia. For this purpose, for each hundred parts of suet from two to four parts of chloride of lime are to be dissolved in from four to eight times its weight of water, and to be mixed warm, and as much dilute sulphuric acid is to be added as is necessary to decompose the chloride.

Suet consists of about three-fourths of stearine, with some elaine, and a little hircin and margarin; the preponderance of stearin renders it the most solid of animal fats, a circumstance which contributes to render it more indigestible than other fats. It liquefies with a gentle heat, and the prepared suet of the Pharmacopœia is obtained by melting it over a slow fire, and straining it, to separate the membranous portion. It is used as an ingredient in cerates, plasters, and ointments.

After being melted, it is little prone to spoiling, and by pouring it over various articles, such as potted char, minced collops, and mushrooms, from which it thoroughly excludes the air, it assists greatly in preserving them.

It has been employed also by M. Ludensdorff for preserving the *fleshy fungi*, or mushrooms, for botanical museums, by boiling them in it (which thus filled their pores and cells, and penetrated the very substance), and then covering them with a coat of varnish. It does not however always succeed in preserving the colour and form. (See Klotsch, in Hooker's 'Botanical Miscellany,' ii., p. 159.)

SUFFERANCE. [TENANT.]

SUFFICIENT REASON. (Mathematics and Physics.) The principle which is connected with these words might be, and frequently is, called the *want* of sufficient reason; and even this term may appear inaccurate, for it should be the want of *any possible amount* of reason. Since, however, all that takes place must have a sufficient reason (whether we know it or not) for its happening, and everything which is asserted must be capable, if true, of being shown to have a sufficient reason, there is no objection to our using the words "want of sufficient reason" in the sense of absolute want of reason, in all matters connected with the exact sciences. If A be equal to B, there must not only be reason, but reason enough for it: anything short of reason enough is no reason at all, and anything short of proof enough is no proof at all.

The use of the word reason in the statement of this principle may itself be fairly objected to. We are in the habit of speaking of mathematical consequences in the same manner as of those to which the notion of cause and effect applies. When one proposition is made to subserve the proof of another, we call the first, one of the reasons of the second, just as we should say that the reason of a flood was the preceding heavy rain. But this mode of speaking must be objectionable if the word reason be used in the same sense in both places. For, first, we are at liberty to deny the effect on denying that cause; if the rain had not fallen, the flood would not have taken place. But when we say that one mathematical proposition is the reason of another, in which position do we stand if we make an hypothetical denial of the first? Simply in that of persons who assert a contradiction of terms, and try to make rational consequences. Thus, the equality of the angles at the base of an isosceles triangle is one of the reasons (so called) why the tangent of a circle is at right angles to the radius; rationally, the first is one of the simpler propositions, the necessity of which, when seen, helps us to see the necessity of the second and more complicated one. But the necessity of the first is not previous to that of the second, except in the order of our perceptions, when we follow Euclid. Suppose we were to ask, if the angles at the base of the isosceles triangle had not been equal, what effect would that circumstance have had upon the position of the tangent of a circle? We might as well inquire what would our geometry have been if two straight lines had been capable of inclosing a space? We remember a book of arithmetic in which it was gravely asked, by way of exercise for the student, "If 6 had been the third part of 12, what would the quarter of 18 have been?" a question which can only be paralleled by "If a thing were both to exist and not to exist at one and the same moment, how many other non-existences would therefore become existences?"

Secondly, the term reason, in the sense of previous cause, is wrong as applied to mathematical propositions, because when any one is made to prove the second, it generally happens that the second, when granted, may be made to prove the first. Thus [RIGHT ANGLE] of the two propositions, "all right angles are equal," and "two lines which coincide between two points, coincide beyond them," one must be assumed, and the other will then follow: but either may be the one assumed; the other will follow. Now it is absurd to say that of two things each is the previous cause of the other. The whole of this confusion may be remedied by any one who will remember that one proposition is not the cause of another, but it is our *perception* of the one which is made the instrument of bringing about our *perception* of the other. The constitution of our faculties is the previous cause of the necessity of mathematical propositions, but not of one before another, though in arriving at the perception of this necessity our cognisance of the necessity of one is made the previous cause of that of the necessity of another. To say that B is the consequence of A, is only to say that our knowledge of the truth of B is the consequence of our knowledge of that of A.

Taking care to use the word reason in the sense just alluded to, we assume that whatever is necessary has a possibility of being shown to be necessary, and that whatever is true has a possibility of being shown to be true. If this be a legitimate assumption, it then follows that whatever it is impossible to show to be true, must be false. But can there be such a thing as a proposition of which there shall be seen, not its falsehood, but the impossibility of demonstrating its truth? Can there arise a case in which we shall be so completely cognisant of all that may possibly be said for or against an assertion, as to affirm a necessary incapability of demonstration of one side or the other? Such cases are universally admitted by mathematicians to exist; and the final assertion which is made on the known impossibility of proving a contradiction, is said to be made on the principle of the *want of sufficient reason*. But this very dangerous weapon is never put into the hands of a beginner, in mathematics at least. And when we call it a dangerous weapon, we do not deny its utility, but we only state what is well known to every mathematical teacher, that a student who is allowed to proceed one step by this principle will soon ask permission to make it the universal solvent of difficulties, and will be quite ready to urge that a proposition *cannot be shown to be false*, in preference to seeking for or following the demonstration that it *is true*. A beginner can easily admit a sound use of this principle, but can hardly distinguish it from the thousand inaccurate applications which his ignorance will make, if it be left in his own hands.

But we can imagine we hear it said that this principle, though sometimes employed in pure physics, is never introduced into mathematical reasoning except *after direct demonstration*, in order to confirm the mind of the learner by making him see how difficult it would have been to imagine the possibility of any contradiction being successfully maintained against the proposition *just proved*. We believe, indeed, that this principle is seldom employed, and always without necessity, so that we could wish its use were entirely abandoned. But we can show that a tacit appeal to it is sometimes made; and this is the worst possible mode of employing it. If the principle be dangerous, and liable to be unsoundly used, it should be most carefully stated when it is used. Whenever we see a proposition assumed, not as an express postulate, but in a definition for instance, or as a self-evident truth, we may trace the operation of this principle on our minds. For instance, take the proposition which is, if there be such a thing in any one proposition, a digest of all the methods of mathematics, namely, that if the same operations be performed on equal magnitudes, the resulting magnitudes are equal. Try to imagine this not true, and want of sufficient reason interferes to prevent success. *What can make a difference?* In this question the principle claims to be applied.

Now, first, in examining the definitions of Euclid, we find an assertion of theorems which we can hardly suppose that Euclid overlooked, though it is very possible that the impossibility of imagining otherwise may have been his guide. For instance, the assertion of the equality of the two parts into which a diameter divides a circle, following immediately upon the definition of a circle; and the definition of equal solids as those which are contained by the same number of plane figures equal each to each. These and such little matters have been, or may be, corrected; but we will now point out a use of the principle which exists in our elementary works of the present day in an unacknowledged form.

In proving the celebrated proposition of Albert Girard relative to the dependence of the area of a spherical triangle upon the sum of its angles, it is assumed that two spherical triangles which have their sides and angles equal, each to each, are equal in area. Now it is easily shown [SYMMETRY] that there may be two such triangles of which it is impossible to make one coincide with the other, nor is any process ever given for dividing each into parts, so that the parts of one may be capable of coinciding with those of the other. Let the angular points of one be placed upon the angular points of the other (which is always possible), and the triangles will not coincide; in common language, they will *bulge* in different directions. When the triangles are so placed, and the common chords drawn, there is no difficulty in seeing that if ever a want of sufficient reason can be granted upon perception, it is for there being any inequality of the areas of the two triangles. And the equality of these areas is accordingly assumed: for instance, in the proposition above alluded to, a pair of unsymmetrically equal triangles always occurs, except when the given triangle is isosceles. And thus the appeal to this principle may be avoided; for it is easy to make the given triangles into the sum or difference of isosceles triangles, in which each of one set is capable of being actually applied to one of the other.

Leaving the subject of pure mathematics, let us now consider the application of this principle in physics. We have observed [STATICS] that the line of separation between pure mathematics and the more exact parts of mathematical physics is very slight indeed: this means as to the clearness and fewness of the first principles, and the rigour of the demonstrations. If we cut the link which ties the sciences of statics and dynamics to the properties of the matter which actually exists around us, we may go farther, and say that we have not only pure sciences, but pure sciences in which the principle of the want of sufficient reason is strictly applicable, because it is our own selves who have, by express hypothesis, excluded sufficient reason. In propositions of pure mathematics, we have seen that we cannot invent or deny for any hypothetical purpose; *is* and *must be*, *is not* and *cannot be*, are synonymes, in all the truths which these sciences teach. But the properties of matter which are not also those of space, are not, in our conceptions, necessary: we can imagine them other than they are, without any contradiction of ideas.

We shall now proceed to consider the point mentioned in STATICS, namely, the character of the axioms of that science. Are they "self-evidently true," and "not to be learnt from without, but from within?" We will not here inquire whether the first must be the second, not being sufficiently clear as to what is meant by knowledge "from without" and knowledge "from within," to enter upon any such investigation. It will do for our purpose to take knowledge "from within" to be a phrase descriptive of such truths as that two straight lines cannot inclose a space, and knowledge "from without" another phrase indicating such truths as are found, say in the facts of political history or geography. Let us separate from the rest one axiom of statics, say "equal weights at the ends of equal arms of a horizontal straight lever balance one another." First, "equal weights" is a synonyme for equal and parallel pressures. We have no objection to placing the idea of pressure on the same footing as that of a straight line, for be the name we give the former conception what it may, it is probable that those powers of communication with the external world which are certainly necessary to the development, at least, of pressure, are not less necessary to that of straightness. Nor are equal pressures difficult of definition; let them be those which are interchangeable, so that either may be put in the place of the other. The rest of the terms of the axiom are geometrical, and to balance each other is to produce no motion,—motion, independently of producing causes, being, we think, as much an idea of geometry as any other. Let A and B be the two ends of a lever (a rigid bar without weight), and C its middle point, which is the pivot; that is to say, the middle point cannot move, the only possible motion of the lever being revolution, in the plane of the pressures, about that middle point. On these hypotheses, we may certainly say that the axiom is self-evident, for want of sufficient reason, that is, of a possibility of sufficient reason for anything in contradiction of it. We have, before the pressures are applied, no cause of motion, by hypothesis: we are to conceive a lever, which, if it move at all, does so by reason of the pressures. We have made these pressures equal, and applied them symmetrically: there is then, and can be, no reason why one should predominate, which does not hold as much of the other. In the very notion of equality of pressures there is interchangeability; that is, each may be substituted for the other without alteration of effect. Suppose then the left-hand pressure to predominate: it will do so if the pressures be interchanged. But after the interchange the same reasons which made the left hand predominate, will make the right hand predominate: or both ends will move in the direction of the pressures, which is impossible.

We believe the preceding to be as legitimate a use as can be made of the sufficient-reason principle; but before statics can be established on axioms, there is another of them required, which we have never been able to satisfy ourselves comes "from within." It must be assumed that the pressure on the pivot is equal to the sum of the pressures on the ends, whatever the length of the arms may be: this we believe *we learn* from existing matter in quite a different sense from that in which we speak when we say that we learn the conception of pressure or of a straight line from our communication with the external world by our senses: to us it more resembles the assertion that the sea is salt, or that a horse has four legs. It certainly does not arise from the sufficient-reason principle; for there is a reason why difference of pressures on the pivots may arise in levers which only differ in the arms, namely, that very difference of the arms. In fact, there is a presumption against the truth of the proposition *à priori*, derived from a principle the frequent and usual truth of which may as well be called knowledge "from within," as the conception of pressure or of a straight line: this principle is, "differences generally make differences, but not necessarily." The beginner in geometry has this in his mind when he feels that he has learnt something in finding out that the sum of the angles of a triangle is always the same, whatever the triangle may be: he would have expected it to be otherwise. Triangles of different sides have generally different areas, different perpendiculars, different inscribed and circumscribed circles, and different angles: why not different sums of angles? In truth it is a constant and latent assumption throughout the exact sciences that "differences are to be supposed to make differences, except where the contrary is proved." And the assumption that the pressure on the pivot of a lever is independent of the arms, is either in defiance of this general principle, or a result of experience.

Thinking, then, that the sciences of pure mechanics can be founded upon few and incontrovertible postulates, in such a manner as to entitle them to the name of pure sciences, or some other which shall mark the real distinction between them and the other sciences of matter, we cannot yet be of opinion that their postulates are all derived from their own evidence, or obtainable from the sufficient-reason principle. There are, however, many points connected with this part of them which are difficult of exposition for want of acknowledged terms.

SUFFIX, a term lately employed in mathematical language to denote the indices which are written under letters, as in a_0 a_1 a_2 a_3, &c. Though these signs have been so long used, we never saw a distinctive name given to them before the publication of Professor Hall's 'Differential Calculus.'

SUFFRAGAN. [BISHOP.]

SUGAR. Referring to SUGAR in the NATURAL HISTORY DIVISION of this Cyclopædia for an account of its distribution in the organic kingdom, and to a separate article [SUGAR CULTURE AND MANUFACTURE] for information concerning the extraction from the sugar-cane, and purification of common or cane-sugar, we shall at present only consider sugar from a chemical point of view.

Sugar—in Persian, *shukkur*, and originally *sarkara* (Sanscrit)—may be defined as a body having a sweet taste, and which, under the influence, direct or indirect, of ferments, splits up into alcohol and carbonic acid. As few plants are wholly destitute of sugar, and as many contain it in considerable proportions, it is not surprising that many so-called varieties of sugar should have been described from time to time. Thus we read of sugar of starch, sugar of raisins, sugar of milk, sugar of gelatine, cane-sugar, grape-sugar, manna-sugar, &c. &c. Many of these, however, have been shown to be identical, and at present nearly all may be included under four varieties, namely: *Sucrose*, or cane-sugar, including sugar from the beet-root, turnip, carrot, maple, birch, palm, Indian corn, and many fruits of tropical plants; *Glucose*, including grape-sugar, starch-sugar, and the sugar generally found in dried fruits; *Fructose*, the state in which sugar exists in recently plucked fruits; and *Lactose*, the sweet principle found in the milk of animals.

Berthelot divides the whole class of sugars, properly so called, into two fundamental groups, of which sucrose and glucose are the respective types. The glucose group is characterised by fermenting directly in contact with yeast; by being destroyed by strong alkalies, even in the cold, and readily at 212° Fahr.; by the reducing action on potassio-tartrate of copper; and by the circumstance that when dried in a water-bath the members of this group are isomeric, having the formula $C_{12}H_{12}O_{12}$. The members of the glucose group differ from each other in their crystalline form; in their rotatory power on polarised light [SACCHARIMETRY]; in the modifications they undergo when exposed to the influence of heat or acids; in the nature of their combinations with water, bases, and chloride of sodium; and in the manner of their conversion into mucic acid, &c. Under the sucrose group, Berthelot includes all sweet principles analogous to cane-sugar; they with difficulty ferment under the influence of yeast; are scarcely changed by alkalies, or by potassio-tartrate of copper, even at a temperature of 212° Fahr.; are, by the action of acids, readily converted into new sugars belonging to the glucose group; and are isomeric only when heated to 266° Fahr., having then the composition $C_{12}H_{11}O_{11}$. The members of the sucrose group are distinguished from each other by their crystalline form; rotatory power; unequal resistance to heat, acids, and ferments; in their behaviour to bodies with which they combine; and in the formation of mucic acid, &c. Sugar of milk (lactose), however, stands in a position intermediate between the above groups; resembling the glucose series in the action of alkalies and copper-salts upon it, it is nevertheless analogous to sucrose in resisting the action of heat and ferments, and capability of being converted into a fermentible sugar.

The four chief varieties of sugar differ slightly from each other in composition, and very widely in appearance and sweetening power. Sucrose has the formula $C_{12}H_{11}O_{11}$, or possibly double that ($C_{24}H_{22}O_{22}$); its appearance and taste are well known. Glucose, or grape-sugar ($C_{12}H_{12}O_{12}+2Aq.$) has considerably less than half the sweetening power of cane-sugar, and is generally met with as a somewhat soft and granular, rather than crystalline mass. Fructose (*chularicose*) ($C_{12}H_{12}O_{12}$) is also less sweet than sucrose, and is, moreover, uncrystallisable. And finally, lactose ($C_{24}H_{24}O_{24}$) occurs in hard, gritty, mammillated crystalline masses, and is considerably inferior in sweetness to any of the other sugars.

Cane Sugar ($C_{12}H_{11}O_{11}$)—is colourless, inodorous, of a purely sweet taste, moderately hard, and brittle. The crystals, when rapidly formed, as in common refined sugar, are small; but when obtained by the slow evaporation of a strong solution, they are of considerable size (sugar candy). The specific gravity of sugar is about 1·6: it undergoes no change by exposure to the air; and, when moderately heated, loses only a little hygrometric moisture: it is soluble in one-third of its weight of cold water, and in all proportions in hot water: a solution saturated at 230° forms, on cooling, a mass of small crystals. It is soluble in alcohol, but much less so than in water; absolute alcohol takes up only 1-80th of its weight, even when boiling, and this separates in small crystals as the solution cools: spirit of wine, of specific gravity 0·830, dissolves nearly one-fourth of its weight. Sugar is phosphorescent when two pieces are rubbed together in the dark. Heated to about 320° Fahr., sugar melts into a viscid colourless liquid, which, cooled suddenly, becomes a transparent mass (barley-sugar); by keeping, it becomes opaque. At 400° to 420° sugar is converted into CARAMEL, or *burnt sugar* ($C_{12}H_9O_9$), two equivalents of water being set free. When exposed to a higher temperature, sugar undergoes decomposition, yielding various gaseous products, and leaving a large proportion of charcoal. Acids produce very different effects upon sugar: thus nitric acid decomposes and is decomposed by it, the principal products being nitric oxide, carbonic, oxalic, and saccharic acids: sulphuric acid, when concentrated, attacks sugar itself, or even a strong solution of it, sulphurous and carbonic acid gases being formed and evolved, and a large quantity of carbon set free; 1-100th of a grain of sugar, on account of the large proportion of carbon which it contains, is capable of imparting colour to an ounce of sulphuric acid. When sugar, dissolved in dilute sulphuric acid, is kept for a long time at a high temperature, it absorbs oxygen from the air, formic acid is produced, and there is deposited a brown insoluble matter termed *ulmin*. Ulmin is sometimes formed when recently expressed cane juice is heated, a small portion of lime, however, neutralises the acid in the juice, and prevents its formation. Hydrochloric acid dissolves sugar, and forms with it a thick black resinous paste. A simple solution of sugar in water undergoes change slowly when exposed to the air, but on the addition of yeast it undergoes rapid fermentation, and is converted, first into grape-sugar, and then into alcohol.

Sugar in many cases combines with the alkalies, earths, and metallic oxides, and, in some cases, forms definite compounds with them called *saccharates*, or *saccharides*. With ammonia, according to Berzelius, sugar combines to form a compound of one equivalent of each; but by exposure to the air the ammonia escapes, and leaves the sugar unaltered: potash and soda appear also to combine with sugar, and they destroy its sweetness; this is restored when the alkalies are saturated with an acid: but if they be left long in contact, the sugar becomes changed into a substance resembling gum.

Lime, baryta, and oxide of lead dissolve in considerable quantity in a solution of sugar: when the first-mentioned of these bodies, in the state of hydrate, is digested at a moderate heat in a solution of sugar, a bitter alkaline solution is obtained, in which the sugar is combined with an equivalent of lime ($CaO, C_{12}H_{11}O_{11}$). Professor Daniell obtained, by the action of these bodies, gum and crystals of carbonate of lime.

The compound of sugar and baryta is similar. When hydrated oxide of lead is digested in a solution of sugar, a yellow alkaline liquid is formed, which yields a tough deliquescent mass by evaporation; but when excess of the oxide is boiled in a solution of sugar, and the liquor is filtered hot, it deposits eventually a tasteless insoluble compound, containing 2 $PbO, C_{12}H_{10}O_{10}$.

Sugar dissolves carbonate and diacetate of copper, forming green solutions which are not decomposed by the alkalies, and this is also the case with the salts of iron. A crystalline compound of sugar and common salt may be formed by the spontaneous evaporation of a solution of four parts of the former and one part of the latter. According to Peligot it contains $NaCe, HO, C_{12}H_9O_9 + C_{12}H_{11}O_{11}$.

Distilled with eight times its weight of quicklime, sugar furnishes Metacetone. Chlorine transforms sugar into a brown substance partially soluble in water.

For the action of solutions of sugar on a ray of polarised light, and estimation of the strength of a solution of sugar, see Saccharimetry.

The uses of cane sugar are too well known to require much notice: on account of its antiseptic power, it is employed to preserve various vegetable products: it is used as a sweetener of many kinds of food, and is in these cases nutritious; but being destitute of nitrogen it is, like other substances similarly constituted, incapable of supporting life for any length of time.

Maple Sugar, when refined, is equal in appearance and sweetening power to refined cane-sugar; and in composition they are similar.

Beet-root Sugar is exactly similar to cane-sugar.

Grape-sugar, or *glucose* ($C_{12}H_{12}O_{12}$, 2Aq.), or *starch-sugar*. Besides the sources previously mentioned, this variety of sugar has been lately shown to be a constituent of healthy urine. Under the name of diabetic sugar it occurs in abnormal quantities in the urine of patients afflicted with diabetes; under these circumstances it is readily detected on adding to a small quantity of the urine contained in a test-tube, first, solution of potash or soda, next a few drops of solution of sulphate of copper, and then gradually heating to the boiling point, when an abundant deposit of red suboxide of copper will be formed if sugar be present in abnormal quantity. The same test may, of course, be applied to any other solution suspected to contain glucose.

Grape-sugar is produced in quantity by allowing a cream of starch and water to flow into water containing one per cent. of sulphuric acid, at a temperature of 130° Fahr. The whole is ultimately boiled for a short time, the sulphuric acid neutralised by chalk, and the solution evaporated down and set aside to crystallise.

Glucose forms combinations with bases which are rapidly decomposed, yielding Glucic Acid. When heated, they yield uncrystallisable Melassic Acid. Combinations of glucic acid with certain crystalline principles occur naturally; several are described under Glucosides.

Heated to about 140° Fahr., grape-sugar softens, and at 212° Fahr. melts, and loses two equivalents of water. At a higher temperature it is converted into caramel. Water dissolves less of grape than of cane-sugar, the solution is less viscid, and it is not so sweet; hot alcohol, however, dissolves more of it, but it is deposited again on cooling in crystalline grains. With sulphuric acid, instead of being charred, as cane-sugar is, it forms a compound acid called *sulphosaccharic acid*, *sulphoglucic*, *sulpholignic*, *vegeto-sulphuric*, or *sulphamidonic acid*, which gives no precipitate with the salts of barium.

Honey contains both fructose, or uncrystallisable sugar, and glucose-sugar. The two may be separated by strong alcohol, which dissolves the fructose and leaves the grape-sugar behind.

Manna Sugar. [Mannite.]

Mushroom Sugar. [Mannite.]

Liquorice Sugar, so-called, is not a true sugar. See Glycyrrhizin.

Sugar of Milk, *Lactine*, or *Lactose* ($C_{24}H_{24}O_{24}$), is obtained by evaporating the whey of milk to its crystallising point; it forms colourless four-sided prisms, which are soluble in about six parts of cold water and two and a half parts of hot: the taste of this sugar is not very sweet, it is unalterable in the air, and is insoluble in alcohol and ether. Boiled with dilute acids, it is slowly converted into glucose. It forms two insoluble compounds with oxide of lead; and reduces boiling solutions of salts of copper, mercury, or silver.

Melitose, *trehalose*, and *melezitose*, are three varieties of sugar lately discovered by M. Berthelot. They are closely allied to cane-sugar. Melitose is contained in Australian manna, a product of the *Eucalyptus*; by fermentation it yields a non-crystalline body, termed *Eucalyn* ($C_{12}H_{12}O_{12}$, 2HO). *Trehalose*, is contained in Turkish manna, a substance formed by an insect (*Larimus nidificans*) at the expense of a plant of the genus *Echinops*; it seems to be identical with the *mycose* of Mitscherlich, a sweet principle contained in ergot of rye. *Melezitose* occurs in Briançon manna, an exudation from the larch tree.

Sorbin ($C_{12}H_{12}O_{12}$) is a sugar contained in the berries of the mountain ash (*Sorbus ancuparia*). Heat transforms it into a deep red matter, termed *sorbinic acid*.

SUGAR CULTURE AND MANUFACTURE. Sugar is a sweet crystallised substance, most commonly prepared from the expressed juice of the sugar-cane, of which there are several species; but sometimes from beet-root, from the sap of one or more species of maple, and from other vegetable productions. Saccharine matter is indeed one of the most common of vegetable secretions, but it is only from the above-mentioned substances that sugar has been extracted to any great extent as an article of commerce; and of these the sugar-cane is by far the most extensively used. The sensation of sweetness is indeed produced not only by many vegetable and animal substances, but also by some of purely chemical character. The muscular parts of all quadrupeds, birds, and fishes, if boiled or roasted soon after death, have a decided though slight degree of sweetness; which sweetness disappears on the commencement of the spontaneous change which ends in putrefactive decomposition. Glycerin is a sweet substance obtainable from most of the fats or expressed oils, whether animal or vegetable, by the process of saponification. The sweet taste of new milk is occasioned by a saccharine substance called sugar of milk. Honey-dew, or aphis-sugar, and the honey of the bee, are intermediate between animal and vegetable sugars; because, though derived from vegetable juices, they are modified by digestion in the stomachs of insects. Among vegetables which contain sugar ready formed (though not in a crystallised or separate state), there are several trees from the sap of which it may be obtained in sufficient quantity for human use. Two of these—the sycamore and the birch—are natives of Britain; but the sugar which they yield is not sufficient to repay the expense of manufacture. The sugar-maple, which abounds in some parts of North America, yields sugar in such abundance as to be of considerable importance. Many trees of the palm family afford a sweet sap, which may be boiled down to a tolerably solid viscid sugar. Saccharine matter exists in many ripe fruits in great abundance, as is evident not only from their sweet taste, but also from the circumstance that it exudes from some, such as the fig and the grape, in the process of drying. Several roots, particularly of the tuberous or fleshy kind, contain sufficient saccharine matter to be commercially important, either for separating it in a pure state, or in the form of an extract of all the soluble ingredients of the root. Of the latter class liquorice is one of the most important. For the former purpose, attempts have been made upon several fleshy roots employed as food. Marggraf (in 1747) tried the skirret (a variety of parsnep), the white beet, and the red beet. His experiments were resumed some years afterwards by M. Achard, at the desire of the Prussian government. Probably these and some other early experiments led, in some degree, to the subsequent introduction of the manufacture of beet-root sugar in France under M. Chaptal.

The above details show how many sources there are from which sugar might be obtained. None of them, however, as far as experiment has shown hitherto, will bear comparison with the sugar-cane in point of cheapness; beet-root sugar indeed has entered into competition with that from the cane, but only successfully when aided by fiscal regulations.

History of Cane Sugar.—Unless we suppose the sacred writers to have alluded to it, Herodotus is probably the earliest author who mentioned sugar. Theophrastus describes three kinds of honey—from flowers, from the air (apparently honey-dew), and from canes or reeds; and in another place he describes a reed or cane that grew in moist places in Egypt, which was sweet even to the roots. From some passages in early writers it would seem that the juice of the cane was used as a drink. The term "honey of canes," which appears to indicate a fluid or semi-fluid consistency, was used by Avicenna, as late as the tenth century. Dioscorides, about the period of the reign of Nero, is said to be the first writer who uses the word *Saccharum* (σακχαρον), or sugar; but though he gives an accurate description of it, he was evidently unacquainted with the process by which it was prepared. He says "it is in consistency like salt, and it is brittle between the teeth like salt." Seneca speaks of sugar as honey found on the leaves of canes, which is produced by the dew, or the sweet juice of the cane itself, concreting; thereby showing the like ignorance of its real character. Pliny speaks of sugar as brought from Arabia, and better from India. "It is," he says, "honey collected from canes, like a gum, white, and brittle between the teeth; the largest is of the size of a hazel-nut. It is used in medicine only." Galen, in the second century, gives a description of sugar almost identical with that of Dioscorides, excepting that he says nothing of its brittleness and resemblance to salt. These qualities are however again mentioned by Paulus Ægineta, in the 7th century, who, following Archigenes, an earlier writer, describes sugar as "the Indian salt, in colour and form like common salt, but in taste and sweetness like honey."

Such notices might be extended much further; but enough has been stated to show that sugar was known, and was an article of commerce, at least as early as the commencement of the Christian era; and also to prove that its origin was very imperfectly understood by ancient Greek and Roman writers. Although more than one writer speaks of sugar as coming from Arabia as well as India, it was probably not made in the former country. Indeed the early Arabian writers themselves speak of sugar as coming from India. It appears probable that the white sugar-candy of China, which has been very long celebrated for its excellence, was the Indian salt of the Roman authors. The historians of the crusades describe the sugar-cane as met with by the Crusaders in Syria. One of these, Albertus Agnensis, about the year 1108, says that "sweet honied reeds," which were called *Zucra*, were found in great quantity in the meadows about Tripoli. These reeds were sucked by the crusaders' army, who were much pleased with their sweet taste; and our author gives the oldest description extant of the process of extracting sugar from the cane. Another of these historians, Jacobus de Vitriaco, in 1124, says that in Syria reeds grow that are full of honey; by which he understands a sweet juice which, by the pressure of a screw-engine, and concreted by fire, becomes sugar. About the same time William of Tyre speaks of sugar as made in the neighbourhood of Tyre, and sent from thence to the farthest parts of the world. As early as the time of the emperor Frederick Barbarossa, sugar was produced in great quantity in Sicily, and used in two states; either boiled down to the consistence of honey, or boiled further, so as to form a solid body of sugar. About 1306, sugar was made in the countries subject to the Sultan, and also in Cyprus, Rhodes, Amorea, Sicily, and other places belonging to the Christians. The progress made in introducing the sugar-cane, and the process of extracting sugar from it, into the islands of the Mediterranean, into Italy, and into Spain, were derived from the Arabs, and were in some degree connected with the increased communication with the East occasioned by the Crusades. It is stated by Venetian historians that in the 12th century Venice could import sugar cheaper from Sicily than from Egypt. The manufacture of sugar was probably introduced into Spain by the Moors. About 1420 the Portuguese took the sugar-cane from Sicily to Madeira; and probably during the 15th century, it was carried from Spain to the Canaries. From these sources, the cultivation of the sugar-cane, and the art of making sugar, were extended by different nations of Europe to the West Indian islands and the Brazils. Wherever the sugar-cane may have been indigenous, there is no reason to question the fact that the manufacture of sugar, derived originally from China and India, was introduced into the western world by the Spanish and Portuguese. In Hispaniola, or St. Domingo, there were, as early as 1518, twenty-eight sugar-works, established by the Spaniards. Peter Martyr, who gives this information, remarks on the extraordinary growth of the cane in that island; which, for a long period, afforded the principal supply of sugar to Europe. Antwerp, about 1560, received sugar from Spain,—which had it from the Canaries; and also from Portugal, the latter country deriving it from S. Thomé and other islands on the African coast, and from Madeira. Sugar was also an article of import from Barbary.

Whatever may have been the precise period of the commencement of the English sugar-manufacture in Barbadoes, Anderson states that in 1627, and for several years later, the Portuguese supplied most parts of Europe with Brazil sugars. About 1650 the British planters in Barbadoes appear to have been realising property very rapidly by the raising of sugar; they having obtained a few years before, valuable information from Brazil respecting the culture and process of extracting sugar from the cane. In 1676 the sugar trade of Barbadoes is said to have attained its maximum, being then capable of employing 400 vessels, averaging 150 tons burden.

Cultivation of the Sugar-Cane.—The botanical characters of the sugar-cane are given under SACCHARUM, in NAT. HIST. DIV., where also the principal species are mentioned. The height attained by the canes, their colour, the length of their joints, and many other particulars, vary with different species, with the character of the soil, and with the modes of culture adopted. The stems vary in height from eight feet up to twenty feet, and are divided by prominent annular joints into short lengths. Long narrow leaves sprout from each joint; but as the canes approach maturity, all the leaves from the lower joints fall off. The outer part of the cane is hard and brittle, but the inner consists of a soft pith, which contains the sweet juice; this juice is elaborated separately in each joint, independently of those above and below it. The canes are usually propagated by slips or cuttings, consisting of the top of the cane, with two or three of the upper joints, the leaves being stripped off. These are planted either in holes dug by hand, or in trenches formed by a plough, from eight to twelve inches deep. Three feet between the rows, and two feet between the holes in the rows, are about the minimum distances; but when the horse-hoe is used to keep the ground clear from weeds, the distances are usually increased to five feet and two and a half feet respectively. Two or more slips are laid longitudinally at the bottom of each hole, and covered with earth from the banks, to the depth of one or two inches. In about a fortnight the sprouts appear a little above the earth, and then a little more earth from the bank is put into the hole; and as the plants continue to grow the earth is occasionally filled in, by a little at a time, until, after four or five months, the holes are entirely filled up. From August to November is generally considered the best time for planting in the British West Indies; and about March and April is perhaps the most generally approved time for cutting the canes, although that operation is sometimes performed through a great part of the year. The maturity of the cane is indicated by the skin becoming dry, smooth, and brittle; by the cane becoming heavy; the pith gray, approaching to brown; and the juice sweet and glutinous. The canes which grow immediately from the planted slips are called *plant-canes;* but it is usual, in the West Indies, to raise several crops in successive years from the same roots; the canes which sprout up from the old roots, or *stoles*, being called *rattoons*. The rattoons are not so vigorous as the original plant-canes; but they afford better sugar, and that with less trouble in clarifying and concentrating the juice. Some planters have, under favourable circumstances, raised rattoon crops for more than twenty years successively, from the same stoles. The canes should be cut as near the ground as possible, because the richest juice is found in the lower joints. One or two of the top joints of the cane are cut off, and the remainder is divided into pieces about a yard long, tied up in bundles, and carried immediately to the mill. The upper branches of the cane are used as food for cattle; the remainder of the waste forms a valuable manure, for which purpose the *trash* or waste from the mill is admirably suited, though much of it is usually consumed as fuel.

Preparation of Raw Sugar.—The operation of cutting the canes is so adjusted as to keep pace with the action of the mill by which the juice is to be pressed out; so that the canes may be crushed or ground while quite fresh. In the East Indies mills of very rude and imperfect construction are used; some of them resembling mortars, formed of the lower part of the trunks of trees, in which the canes are crushed by the rolling motion of a pestle, moved by oxen yoked to a horizontal bar. The expressed juice runs off by a hole bored obliquely from the lower part of the mortar-like cavity, and is conducted by a spout to a vessel placed to receive it. In order to make such a mill effective, it is necessary to cut the cane into very small pieces. Other mills are capable of being moved from place to place, so that they may accompany the movements of the cane-cutters. One of these consists of two vertical rollers of hard wood, having, near their upper ends, endless screws, or spiral ridges, so fitting into each other that both rollers may revolve when rotatory motion is applied to either. The axis of one of the rollers is prolonged vertically above the framing, and carries a beam to which oxen are yoked to turn the mill. This appears to be the prototype of the vertical mill long used in the West India colonies. Another, still simpler, consisting of two grooved rollers placed horizontally in contact with each other, and turned by the power of men applied to levers at their ends, appears, in like manner, to be the rude original of the improved horizontal mills introduced of late years. The common vertical cane-mills of the West Indies consist of three rollers, usually of wood, with narrow strips of iron attached to their faces, so as to form, by the spaces left between them, straight grooves extending from end to end of the rollers. The moving-power is applied to the middle roller, and communicated from it to the others by cogged wheels. Of late steam-engines have been adopted with good effect in some of the sugar-works in the West Indies. In using the mill, a negro applies the canes in a regular layer or sheet to the interval between the first and second rollers, which seize and compress the canes violently as they pass between them. The ends of the canes are then turned, either by another negro on the opposite side to the feeder, or by a framework of wood called a *dumb returner*, so that they may pass back again between the second and third rollers. As these are placed nearer together than the first and second, they compress the canes still more, so that on leaving them they are reduced to the form of dry splinters, which are called *cane-trash*. Channels are added to receive the liquor expressed from the canes, and to conduct it to the vessels in which it is to undergo the succeeding operations.

The construction of this mill is very defective. A better form is that of placing the rollers in a horizontal position, and feeding the mill by sliding the canes gradually from an inclined board. The rollers, made very accurately of cast-iron, and fluted or grooved on the surface, are not placed in the same plane, but are arranged in a triangular form, the periphery of the upper roller being very nearly in contact with the two lower rollers, which are also very near together. The two lower rollers, which are called respectively the feeding and delivering rollers, have small flanges at their ends, between which the top roller is placed, so that the pressed canes may not be able to escape from the rollers and clog the machinery. The feed-board is an inclined plane, commonly of cast-iron, the edge of which is nearly in contact with the feeding roller. The delivering board, which receives and conducts away the *trash* of the cane, is also of cast-iron, sloping downwards from the delivering roller. In some cases the liquor is raised from the gutter of the mill-bed by pumps connected with and worked by the machinery of the mill. Where circumstances render such an arrangement practicable, labour may be saved by placing the crushing-mill on a high level, so that the liquor may run from it to the vessels in which it is to be purified, by inclined gutters. In Demerara a well-constructed engine and mill will produce about a hundred gallons of liquor per hour for each horse-power.

Cane-juice, as expressed by the mill, is an opaque, slightly viscid fluid, of a dull gray, olive, or olive-green colour, of a sweet balmy taste, and of a specific gravity varying from 1·033 to 1·106. It holds in suspension particles of solid matter from the cane, a considerable portion of which is separable by filtration or repose. The juice is so exceedingly fermentable, that in the climate of the West Indies it would often run into the acetous fermentation in twenty minutes after leaving the mill, if the process of clarifying were not immediately commenced.

We have next to treat of the extraction of the sugar from the juice. As practised in the East Indies, the liquor, after being strained so as to separate the coarser feculencies, is boiled down in open boilers into a thick inspissated juice; the scum which rises during the operation being removed. When it is sufficiently evaporated, it is removed into earthen pots to cool, and in these it becomes a dark-coloured, soft, viscid mass, called *goor*, or *jaggery*. Much of the molasses or uncrystallisable part of the juice is then separated, by putting the goor into a coarse cloth and subjecting it to pressure. The sugar is further purified by boiling it with water, with the addition of an alkaline solution and a quantity of milk. When this has been continued until scum no longer rises upon the liquor, it is evaporated, and sometimes strained, and afterwards transferred to earthen pots or jars. After it has been left for a few days to granulate, holes in the pots are unstopped, and the molasses drains off into vessels placed to receive it. The sugar is rendered still purer and whiter by covering it with the moist leaves of some succulent aquatic plant, the moisture from which drains slowly through the sugar, and carries with it the dark-coloured molasses. A similar process to the above is said to be practised in Cochin China.

The separation of the sugar from the cane-juice is effected in a much simpler manner in the West Indies. The juice is conducted by gutters from the mill to large flat-bottomed pans, called *clarifiers*. Each of these is placed over a fire, which may be regulated or extinguished by a damper; and each is supplied with a stop-cock or siphon for drawing off the liquor. When the clarifier is filled with juice, a little slaked lime is added to it; the lime, which is called *temper*, being, in most cases, previously mixed with a little cane-juice to the consistence of cream. As the liquor in the clarifier becomes hot, the solid portions of the cane-juice coagulate, and are thrown up in the form of scum. The proper heat is indicated by the scum rising in blisters and breaking into white froth, which commonly happens about forty minutes after the fire is lighted. The damper is then closed, and the fire dies out; and after an hour's repose, the liquor is ready for removal to the first of the evaporating pans.

From the clarifier the purified juice, bright, clear, and of a yellow wine colour, is transferred to the largest of a series of evaporating pans, three or more in number. These evaporators are placed over a long flue, heated by a fire at one end, over which the smallest of the coppers, called the *teache*, is placed. In the process of boiling, impurities are thrown up in the form of scum, which is carefully removed. In the *teache*, the liquor is boiled down to as thick a consistency as is considered necessary for granulation; this point being most commonly ascertained by observing to what length a thread of the viscid syrup may be drawn between the thumb and finger. This trial by the *touch*, whence the teache is supposed to derive its name, is very imperfect; for it sometimes happens that the syrup may have the required tenacity, and yet not be in a good state for crystallising. The latter point may be better ascertained by observing the incipient granulation of the syrup on the back of a ladle dipped in the teache. The thermometer, though useful, will not be a sure guide in determining the proper moment for *striking*, or emptying the teache; because a viscous syrup, containing much gluten and sugar, altered by lime, requires a higher temperature to enable it to granulate than a pure saccharine syrup. The concentrated syrup is ladled, or *skipped*, from the teache, either immediately into open wooden boxes called *coolers*, or into a large cylindrical cooler, from which it is afterwards transferred to the granulating vessels. In these the sugar is brought to the state of a soft mass of crystals, imbedded in thick, viscid, but uncrystallisable fluid. The separation of this fluid is the next process, and is performed in the *curing-house*. This is a large building, the floor of which is excavated to form the molasses reservoir. Over this cistern is an open framing of joists, upon which stand a number of empty *potting-casks*; each of these has eight or ten holes bored through the lower end, and in each hole is placed the stalk of a plantain-leaf. The soft concrete sugar is removed from the coolers into these casks, in which the molasses gradually drains from the crystalline portion, percolating through the spongy plantain-stalks.

When it leaves the curing-house the sugar is packed in hogsheads for shipment as *raw*, *brown*, or *muscovado sugar*; and in this state it is commonly exported from our West Indian colonies. As the molasses is very imperfectly separated from the crystallised sugar, a considerable diminution of weight takes place subsequent to the shipment, by the drainage from the hogsheads. This waste has been estimated to amount to no less than 12 per cent. The loss upon French colonial sugars used to be much greater even than this. Means have, however, been adopted of late years in some colonial sugar-works for reducing this loss.

Clayed sugar, also called *Lisbon sugar*, is raw sugar that has been subjected to a peculiar operation. The sugar is removed from the coolers into conical earthen moulds called *formes*, each of which has a small hole at the apex. These holes being stopped up, the formes are placed, apex downwards, in other earthen vessels. The syrup, after being stirred round, is left for fifteen or twenty hours to crystallise. The plugs are then withdrawn, to let out the uncrystallised syrup; and, the base of the crystallised loaf being removed, the forme is filled up with pulverised white sugar. This is well pressed down, and then a quantity of clay mixed with water is placed upon the sugar, the formes being put into fresh empty pots. The moisture from the clay, filtering through the sugar, carries with it a portion of the colouring-matter, which is more soluble than the crystals themselves. When the loaves are sufficiently purified to be removed from the formes, they are dried gradually in a stove, and crushed into a coarse powder for exportation. Claying is little practised in British plantations, from an opinion that the increase of labour and diminution of quantity of produce occasioned by it are not compensated by the improved quality of the sugar. It was however very generally practised by the French in St. Domingo. Hague's process consists in submitting the raw sugar, after being cured in the usual way, to the action of a vacuum filter. The apparatus consists of a shallow vessel, beneath which is a cavity connected with an air-pump. The bottom of the vessel is perforated with a number of small holes; and when a quantity of muscovado sugar, mixed with a little water into a pasty mass, is laid in it, upon a piece of haircloth, the air is withdrawn from the cavity beneath the sugar. The pressure of the superincumbent atmosphere upon the surface of the sugar then drives the moisture, and with it much of the colouring-matter, through the holes in the bottom of the vessel. When the sugar is sufficiently whitened, the air-pump is stopped, the sugar and molasses are removed, and a fresh charge of muscovado is applied. Another means of avoiding the loss consequent on the drainage from raw sugar during its voyage to this country, is the importation of sugar for the use of the refiner, in the form of concentrated cane-juice, containing nearly half its weight of granular sugar along with more or less molasses, according to the care taken in the boiling operations.

Before proceeding to the subject of sugar refining, it may be well to make a few observations on suggested improvements in the West Indian treatment of raw sugar. Chemists, and the better class of sugar-growers, have long known that a large amount of sugar is wasted by an imperfect management of the operations at the plantations. It is believed that 25 per cent. of the juice lodges in the cells of the megass or trash, and is lost; it ought to be extracted, but is not. Even if not, the trash might form a better fuel for the boiling-houses (where it is now used) if first dried by the surplus heat of the chimneys, &c. Dr. Scoffern, in 1847, ascertained that, in various ways, no less than two-thirds of the sugar is in some instances lost. In 1849 he introduced certain improvements, intended, by the use of new defecating agents, to increase the quantity of juice obtained from the cane, and of sugar obtained from the juice. Some of the agents used by him are poisonous however in their natural state, though innocuous in the process; and this seems to have retarded the acceptance of his method. Some inventors say that the weight of juice extracted is only 50 per cent. of the weight of the original cane, whereas it ought to be 90 per cent.; and they have devised a mode of treating the megass with hydraulic pressure, after the mill has done its work; by this means the megass becomes a flattened mass of trash, as hard and nearly as dry as a deal board. It is also believed that, by a better construction and management of apparatus more sugar and less molasses [MOLASSES] might be obtained from a given weight of juice.

Sugar-trash has been tried in England as a material from which to make paper, but without much success.

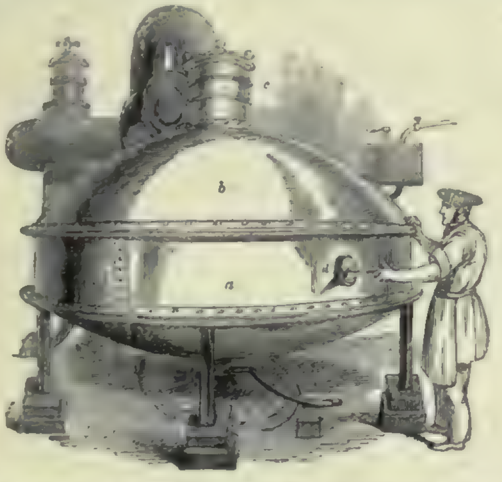
Sugar-refining.—Raw or muscovado sugar, as brought from the colonies, forms the common *moist* or *brown* sugar of the shops. The saccharine particles are always mixed with other matter, which imparts to the sugar a dark colour, a moist clammy feeling, and an empyreumatic odour. The object of the sugar-refiner is to remove these impurities, so as to obtain the sugar in the hard white semi-transparent state known as *loaf-sugar*.

The art of refining sugar, as well as that of extracting it from the cane, is supposed to have been brought to Europe from the East, probably from China; but at what time is uncertain. The Venetians are believed to have been the earliest sugar-refiners in Europe; and it is known that they practised the art before the discovery of America. The Venetians originally operated upon the coarse black sugar brought from Egypt, and followed the Chinese practice of converting it into sugar-candy before they made loaf-sugar. Stow ('Survey of London') states that sugar-refining was commenced in England about 1544. There were then two sugar-houses in London, but they yielded little profit, because there were many sugar-bakers in Antwerp who could supply refined sugar to England better and cheaper than it could be made at home. Subsequently, the commerce between England and Antwerp being stopped, these two sugar-houses supplied all England for twenty years, and became so profitable, that many other persons embarked in the business.

Few manufacturing operations have undergone more important changes than that of sugar-refining. As generally practised until within a recent period, the process commenced by mixing the raw sugar in a large open copper with lime-water, and adding to the mixture when warm a quantity of bullock's blood. The heat occasioned the serum of the blood to coagulate, and in so doing to collect most of the impurities floating in the liquor, and to raise them with it to the surface of the syrup in the form of a thick scum, which was carefully removed. This clarifying process was sometimes repeated with a fresh quantity of blood, or, as it is technically called, *spice*. When the liquor was thus rendered tolerably clear, and was partially evaporated by boiling, it was further cleansed by passing it through a filter of thick woollen cloth, which detained any particles of scum that might have been left after skimming the liquor. It was afterwards concentrated by boiling in a smaller open copper till sufficiently thick for graining; after which it was formed into loaves in the manner hereafter described. For loaves of the finest quality a second refining followed this. In the preceding section allusion has been made to the methods of separating molasses from raw sugar by the vacuum-filter and the hydraulic-press, both of which have been applied to the preparation of sugar for refining; by the latter process sugar is now capable of yielding loaves equal to double-refined by one process.

Many improvements have been effected upon the old methods of clarifying and concentrating the syrup. The raw sugar is transferred from the casks into large circular *blow-up cisterns*, in which it is mixed with lime-water. The mass is heated by steam, forced by its own pressure through small apertures in copper pipes, which are laid along the bottom and sides of the vessel; and the perfect solution of the sugar is aided by stirring with long poles. The liquor is allowed to flow from the blow-up cistern to a range of filtering-vessels in a room beneath. The filters are tall vessels six or eight feet high, of cast-iron or wood, having cisterns at top and bottom; and a number of cloth or canvas tubes, closed at their lower ends, but communicating at their upper ends, by which they are suspended, with the upper cistern. Within each of these tubes is a bag of thick close cotton-cloth, which, being much larger in diameter than the tube in which it is enclosed, is necessarily folded together. By this device a very extensive filtering surface is obtained in a small compass; and, as the liquor from the upper cistern cannot escape from the bags except by percolating through the meshes of the cloth, it becomes, as it drops into the lower cistern, very clear and transparent; most of the solid impurities remaining in the bags. On leaving the filter, the syrup, though clear and transparent, is of a reddish colour; and the removal of this tinge is effected by filtering the syrup through a mass of powdered charcoal. The application of the bleaching power of charcoal to the purification of sugar is one of the great improvements effected by modern science. Powdered animal charcoal is placed in a large square vessel, which has a perforated false bottom, to the thickness of nearly three feet. The syrup is conducted by pipes from the bag-filter to the surface of the charcoal, through which it percolates slowly; it then drops through the holes into the cavity beneath, where it is found almost colourless. In some cases, before the sugar is placed in the blow-up cistern, it is partially purified by mixing it into a pap with hot water or steam, and exposing it to drain in large sugar-moulds, similar to those used in the preparation of clayed sugar. In this case the purification may be rendered more complete by the filtration of moisture from a magma of sugar (a mass of wet sugar in a state resembling mortar), applied in the same way as that of clay in the claying process. Sometimes also a little blood is mixed with the sugar in the blow-up cistern; or, instead of it, a mixture of gelatinous alumina and gypsum, called *finings*. Other refiners use both the blood and finings.

In the concentration of the clarified syrup, which forms the next process, improvements of the greatest importance have been effected. In the old plan of concentrating the syrup in open pans, they were heated by fires to a temperature of from 230° to 250° Fahr. Many plans were contrived for rendering the application of heat more regular and controllable. It is well known that fluids will boil at a much lower temperature in a partial vacuum than when exposed to the ordinary pressure of the atmosphere; and by the happy application of this principle, Mr. Howard removed the chief difficulties attending the evaporation of saccharine syrup. The accompanying cut, which represents one of the *vacuum-pans* constructed on Howard's principle, may assist in the explanation of this admirable contrivance. The apparatus consists of a copper vessel, *a*, *b*, the several parts of which are united by flanges, with packing between the joints to render them perfectly air-tight. The middle portion, *a*, is cylindrical, from six to seven feet in diameter; and the upper part, *b*, is convex or dome-shaped. The bottom is also convex, but in a less degree. The bottom is double, the cavity between the inner and outer casings forming a receptacle for steam. The best kinds of pans have also a spiral coil of copper pipe a little above the inner bottom, by which steam may be made to circulate through the body of syrup in the pan, and thereby assist evaporation. The bottom cavity is supplied with steam generated at a low pressure; but the spiral pipe contains steam of high pressure, and consequently of great heat. There is a short broad pipe called the *neck*, rising from the dome, from which a communication is formed with an air-pump, by which the pan may be partially exhausted of air. A communication is also formed between the interior of the pan and a vessel containing clarified syrup. A quantity of liquid sugar is admitted. The air-pump continues at work during the boiling of the syrup, motion being communicated to it from a steam-engine; and by this means the sugar is enabled to boil at a temperature of only 130° to 150°, or 100° lower than that required in open vessels. To ascertain when the syrup is sufficiently evaporated, the pan is supplied with a very ingenious appendage called the *proof-stick*, the handle of which is shown as held by an attendant. It consists of a tube extending into the pan, and terminating in a peculiar kind of valve, so formed that, by turning a rod inserted in the tube, a sample of sugar may be drawn out without admitting air into the vessel. The sample thus obtained is tried by the *touch*, as described in explaining the process of evaporation in the West Indies; and when it appears to be in a satisfactory state, the sugar is allowed to flow, through an opening in the bottom of the pan, into a granulating-vessel in a room below.



The practice of boiling the syrup at so low a temperature has occasioned a curious difference in the next process, which is that of granulating the concentrated liquor. In the West Indies, the vessels used for this purpose are called *coolers*, because the syrup is brought down to a lower temperature than in the boiling-coppers. The corresponding vessels used in refining sugar upon the old plan were similar to these, and were called by the same name; but when the method of boiling at a low temperature is adopted, the granulators become *heaters* instead of *coolers;* the sugar, when placed in them, being raised to a temperature of 180° or 190°. This is done by the admission of steam into a cavity surrounding the granulating-vessel, a shallow open copper or pan, in which the thick pulpy mass is stirred quickly to promote the granulation.

From the granulators the sugar is transferred, by means of copper basins or pans, into moulds of a conical form, usually of iron. These moulds have orifices at their points, which are stopped up before they are filled with sugar. They are arranged with their open bases uppermost; and immediately after the sugar is poured in it is stirred round, to diffuse the crystals equally through the semifluid mass. They are then left for several hours, that the sugar may become solid: after which they are removed to another room; and, their points being unstopped, they are set in earthen jars, that the uncrystallised fluid may drain from them; or the same purpose is effected by placing them in racks, with gutters to receive the syrup. This syrup is re-boiled with raw sugar, so as to yield an inferior quality of sugar; and when all the crystallisable matter has been extracted from it, the remainder is sold as *treacle*. It was formerly usual to "clay" the loaves in order more thoroughly to remove the molasses; but this process is abandoned by most refiners for the superior method introduced by Mr. Howard of cleansing the loaf by causing a saturated solution of sugar in water to percolate through it. When the loaf of sugar is thoroughly purified by the repetition of this process, and is sufficiently dry, it is turned out of the mould; the base being scraped to an even surface, and the apex applied to a kind of lathe, in which any part that may be slightly discoloured is cut off, leaving the end clean and smooth. The loaves are finally dried in an oven heated by steam-pipes to a temperature of 130° or 140°, and then wrapped up in paper for sale.

It is needless to follow the processes by which the syrups and other refuse of the best sugar are converted into sugars of inferior quality, which are either sold as cheap loaf-sugar, or formed into large coarse loaves called *bastards*, which are crushed into powder for sale. It has been asserted that about two-thirds of the molasses found in the moulds under the old system were formed by the intense heat employed in concentrating the syrup; a loss which is now, in a great measure, obviated. The effect of these improvements in diminishing the price and consequently increasing the consumption of refined sugar, is also very important; the cost of refined sugar being now only about 20 per cent. greater than that of raw sugar, although formerly the difference of price was as much as 40 per cent.

In the preparation of refined sugar, as in that of raw, many improvements have recently been introduced; but none equal in importance to Howard's capital invention of the vacuum pan. The chief of them is the draining of the sugar-loaves by centrifugal motion, on the system now so largely adopted in many branches of manufacture. [DRYING MACHINES.] Several sugar moulds, with crystallised wet sugar in them, are arranged in a horizontal circle, each with its open apex outwards; the frame containing them is made to rotate 800 times in a minute, and the centrifugal force thus generated drives all the moisture out of the sugar and out of the mould. Or the wet mass may be put at once into a centrifugal machine, and whirled round until it becomes a nearly dry white powder. In either case there is a great saving of time over the old method. Van Goethem, a Belgian sugar refiner, has been the chief agent in bringing about this improvement.

Sugar-Candy.—This is the only kind of refined sugar made in China and India; and is made of the finest quality by the Chinese, who export it in considerable quantities. Two sorts are met with at Canton, called, respectively, Chinchew and Canton; the former being the produce of the province of Fokien, and the latter of that of Canton.

Of these, the former is by far the best. Chinese sugar-candy is consumed, to the almost total exclusion of other sugar, by the Europeans at the settlements in the East. The process of making it is briefly described under CANDY.

Beet-root Sugar.—The process of manufacturing sugar from beet is described under BEET. The manufacture was commenced in Europe chiefly through the high price of colonial sugar, owing partly to war and partly to taxation. The early attempts were disastrous: but within the last few years the manufacture has greatly extended. Stollé, of Berlin, estimated the quantity of beet sugar exported from the countries where it was made, at about 2,300,000 cwt. annually; but this affords no index to the quantity *made* and *consumed* in those countries. It is known that 20,000,000 centners of beet-root have been used for the manufacture in Germany alone in one year. In France, also, the number of beet-sugar manufactories is very large. The relative advantages and disadvantages of beet-sugar have long been, and still are, a matter of controversy. Stollé claims for beet-sugar made in Europe, over cane-sugar made in slave countries, the following advantages: superior intelligence and skill of the operatives; superiority and easy repair of machinery; ready intercourse of the manufacturers with chemists and mechanical inventors; the presence of the owners instead of entrusting the management to agents; a ready supply of labour and skill of various kinds; and a climate less likely than that of tropical countries to produce fermentation in the saccharine juice. Very favourable balance sheets have frequently been put forth by beet-sugar makers; but these, like many other kinds of balance sheet, require to be received with caution.

We may here add a few words concerning sugar from the *maple* and the *Sorghum saccharatum.*

Maple-sugar is made in Canada and the United States. The sap is obtained by boring holes in the trunk of the maple-tree, in a direction inclining upwards, with an augur about three-quarters of an inch in diameter: the depth of the holes being such that they may penetrate about half an inch into the alburnum, or white bark, as the sap is found to flow more freely at that depth than at any other. Tubes of elder or sumach are inserted in the holes, so as to project a few inches from the trunk; their outer ends being cut so as to form small troughs, along which the sap trickles into receptacles placed beneath them. The season for collecting the sap extends from the beginning of February to the middle of April. Though collected in frosty weather, the tendency of the juice to fermentation renders it desirable to boil down the sap within two or three days at furthest from the time of its extraction. This is done in very rude apparatus, which is carried to the encampment formed by the sugar-makers. The syrup is thus brought to about one-third of its original bulk, the scum which rises being removed. White of egg is sometimes used as a clarifier; and occasionally a little butter or fat is thrown in during the last boiling. The molasses are separated, though mostly in a very imperfect manner, by filtration. The concreted sugar is said to be equal in taste to cane-sugar, and to sweeten as well. It is seldom refined, but is capable of being made equal to loaf-sugar from the cane.

The *Sorghum saccharatum*, or Sugar Grass, has lately become an object of attention. Seeds were brought from China, and distributed in France, Belgium, Germany, England, and the United States. Some were sown in a market-garden at Streatham, in October, 1858; the plants grew to a height of 10 feet; and the juice was said to contain 13 per cent. of saccharine matter. Dr. Scoffern even asserted that every acre of inferior sandy land in England might be made to yield 4½ tons of sugar from this source; that in bad years the plant might be sliced in November, dried, and used for fodder, instead of turnips; and that it is superior to the white beet and the sugar-maple as a source for sugar. This high encomium, however, has not been verified. The plant, nevertheless, is more easily cultivated than the sugar-cane, and over a wider variety of soil; and as the juice is contained in stems capable of being sliced, there is no occasion for a sugar-mill. On the other hand, Dr. Hayes, of the United States, from experiments made in 1857, found that the syrup would not crystallise properly: whence he inferred that the plant secretes, not true sugar, but a semi-fluid glucose. At any rate, the plant is worthy of further attention in Europe. It is said that the first seeds were brought from Shanghai to Paris in 1851, that all died but one, and that all the plants of the *Sorghum* now being grown for this experiment in Europe and America are the produce of this one seed.

Sugar-Trade.—It is not known how much sugar is made in the world. Stollé, in 1853, put down the quantities of cane-sugar *exported* from the several countries as follows:—

East and West Indies (British)	7,030,000 cwts.
French colonies	1,290,000 ,,
Dutch colonies	1,300,000 ,,
Spanish colonies	6,650,000 ,,
Danish colonies	150,000 ,,
Brazil	4,000,000 ,,
United States	2,730,000 ,,
	23,150,000 ,,

To which he added about an equal quantity consumed in those same countries. He also put down in his tabulation, 3,300,000 cwt. of beet-sugar, 2,000,000 of palm-sugar, and 400,000 of maple-sugar. If these estimates are approximately correct, the total sugar product would be over 50,000,000 cwts. Mr. M'Culloch has expressed an opinion that, in 1858, the produce of cane-sugar all over the world was 1,250,000 tons, equal to 25,000,000 cwts.—an estimate so much lower than that of Stollé for 1853, as to show that the authorities rely on very different data. Mr. M'Culloch credits Cuba with one-third of all the cane-sugar grown in the world.

In 1661 a duty amounting to 1*s.* 6*d.* per cwt. was imposed on the importation of British plantation sugar in England; and in 1669 the duty was doubled. This gradually rose to 30*s.* early in the present century, from which it fell to 24*s.* in 1833. From 1793 to 1808, the duty on East India sugar was 37 and 38 per cent. ad valorem, and afterwards was 11*s.* and 8*s.* the cwt. higher than the duty on West India; but by an act passed in 1836, the duties were assimilated by the reduction of East India sugar from 32*s.* to 24*s.* the cwt. The duty on foreign sugar varied from 60*s.* to 63*s.* until about 1844.

Fluctuations in price, and the domestic circumstances of the country, occasion great diversities in the consumption of different years. Thus, with the low price of 1831, the consumption was greater than in 1839, notwithstanding the population of Great Britain had increased nearly 2,000,000. The annual consumption averages above 20 lbs. per head for England and Scotland, and would probably be 50 lbs. if a great reduction were to take place in the price. In France the annual consumption averages 5 lbs. per head; in the states of the German League, above 4 lbs.; and in the whole of Continental Europe, about 2½ lbs.

The quantity of sugar produced in the West Indies has fluctuated greatly since the emancipation of the slaves. The equalisation of the duty on East India sugar in 1836 gave a stimulus to the cultivation of the sugar-cane in the East Indies, and the import of 1840 exceeded all expectation, being 1,066,032 cwts., or above 53,000 tons. The scarcity of 1840 was so great that 2316 cwts. of foreign sugar were entered for home consumption, paying a duty of 63*s.*, or 39*s.* the cwt. more than sugar from British possessions. The sugar of Brazil, Cuba, and other foreign countries is chiefly exported to the Continent, where the price is on an average from 10*s.* to 20*s.* the cwt. lower than in this country.

In 1844 a great change was effected in the sugar duties, whereby foreign sugar might, under certain circumstances, be imported at a duty of 34*s.* instead of 63*s.*, and in some favoured instances (to encourage free instead of slave labour) as low as 23*s.* 6*d.* Sugar from foreign slave states was still to pay 63*s.* Sugar from British possessions was to pay 14*s.* to 21*s.*, according to quality. By acts passed in 1846 and 1848, the duties on British and foreign sugar were gradually to approach equality, the equalisation to be completed in 1854, at which date all sugars would pay from 10*s.* to 13*s.* 4*d.* per cwt., according to quality. Between 1854 and 1858 the duties were slightly raised, to meet a war expenditure; during this interval, the lowest duty on the lowest kind was 11*s.*; and the highest duty on the highest kind, 17*s.* 6*d.* By the tariff of 1860, the duty was still again slightly raised, ranging from 12*s.* 8*d.*, for common moist, to 18*s.* 4*d.*, for best refined: cane-juice paid a duty of 10*s.* 4*d.* These duties are the same, whatever country the sugar may be brought from.

Without taking note of the quantity re-exported, the following gives the quantity of sugar imported for home consumption, and the duty raised from it, in six different years, situated respectively five years apart:—

	Entered for Home Consumption.	Amount of Duty.
1833	3,600,000 cwts.	£4,400,000
1838	3,900,000 ,,	4,700,000
1843	4,000,000 ,,	5,100,000
1848	6,100,000 ,,	4,600,000
1853	7,300,000 ,,	4,100,000
1858	8,500,000 ,,	5,800,000

The above quantities are given in round numbers; but to illustrate the present state of the trade, the figures for 1860 will here be given in more detail:—

	Imported.	Home Consumption.
Unrefined, 1st quality	86,516 cwts.	48,505 cwts.
,, 2nd quality	4,743,286 ,,	3,464,999 ,,
,, 3rd quality	4,037,784 ,,	5,184,093 ,,
Total unrefined	8,867,586 ,,	8,697,597 ,,
Refined and sandy sugar	245,041 ,,	266,064 ,,
Cane juice	18,286 ,,	12,026 ,,
Molasses	646,765 ,,	559,953 ,,
	9,777,678 ,,	9,535,640 ,,

It will thus be seen that the home consumption of sugar very nearly equals the imports, leaving only a small quantity for re-exportation. The computed real value of the whole (minus the duty) was about 18,000,000*l.*

SUGAR, PROPERTIES OF. Sugar is a proximate principle, chiefly of vegetables, but also sparingly of animals of the class Mammalia. It presents considerable varieties, according to the source whence it is obtained, and is distinguished into those which are capable of undergoing the vinous fermentation, and into those which are not; also into those which can assume a definite crystalline form, and those which cannot; but sometimes these two kinds co-exist in the same sort, as in the sugar from the sugar cane, which yields both the finest crystals and likewise molasses or treacle. It almost invariably exists in a dilute and liquid state in plants, but it occasionally exhibits a crystalline form in the flower of certain plants, such as the *Rhododendron ponticum*, the *Strelitzia Reginæ*, and *Eucomis punctata*. Sugar is the great principle by which rapidly-growing succulent parts of plants and seeds, when they germinate, are nourished. Hence it is produced in large quantities in such seeds as contain starch, when excited to germinate, as may be observed in the process of malting, which up to a certain stage is exactly that of the germination of the seed. Under these circumstances, seeds which are insipid from the bland nature of the starch which they contain become sweet. By this means many seeds which are regarded as little suited for the nourishment of man may be made to contribute to his support, by merely steeping them in water till they sprout. A similar transformation of starch into sugar takes place in the ripening of many fruits. Thus the fruit of the banana, or plaintain, which, when gathered green, abounds in starch, if allowed to ripen on the stalk is destitute of starch, and yields much gummy and saccharine matters. The same happens when the palms are about to flower, as all the starch in their lofty stems is rapidly transformed into sugar; and hence the sago-palm (*Sagus Rumphii*, &c.) and the *Mauritia flexuosa* (sago-palm of the Orinoco) are cut down just when the flower-buds begin to appear, to obtain the sago they contain. In other palms the flower-buds are allowed to protrude, and a wound being made in the spatha, a large quantity of a sweet fluid distils, which may either be concentrated by boiling, when sugar is deposited, or the liquid may be fermented, and so yield the *toddy* called *palm wine*. If these, or the sugar-cane, maize, or our common esculent roots, parsnep, skirret, carrot, or beet, are allowed to flower, all the gummy and saccharine matters disappear from the roots or stem. The transformation of starch into gum and sugar is effected by a principle called *diastase* [FERMENT], which is so powerful, that "one part of it is sufficient to render soluble the interior portion of two thousand parts of starch, and convert it into sugar." Wherever buds are lodged, there the elements of diastase are placed, to come into play, when they begin to sprout, and supply them with food in a state of solution, as is the case with the buds or eyes of potatoes.

Many seeds, before they are ripe, contain a saccharine substance, which is changed into starch when fully ripe, but which again becomes sugar in germinating, such as the garden pea. Many stems of grasses are sweet at an early stage of their growth, but become insipid at a later period. This influences greatly the nutritive powers of these grasses, according to the stage of growth when they are cut down and made into hay. (See appendix to Davy's 'Agricultural Chemistry.') Those which have been allowed to become too ripe are often restored to a proper state by the fermentation (*heating*) which occurs after the hay is stacked; but this is sometimes so violent as to consume the rick.

The starch lodged in the stem of certain trees in autumn is converted, by the ascending sap in spring, into sugar, with great rapidity. This is the case with the *Acer saccharinum*, or sugar-maple, and many other species of that genus which are tapped in February.

The same is the case with the ascending sap of the birch-tree, but this does not contain sufficient sugar to permit the concentration of it; there is enough however to undergo the vinous fermentation, and thereby furnish the agreeable beverage called *birch wine*.

Next to the sugars from the cane and beet-root, among those which are crystallisable and capable of fermentation, the most important is the *granular* sugar obtained from a great variety of sources. It exists in considerable quantity in the juice of grapes, and hence the name *grape sugar*, which should be limited to this particular variety, is sometimes extended to the whole class of krummel sugars. It forms a constituent of a great many fruits, not merely fleshy, such as pears, cherries, peaches, melons, dates, figs, grapes, on which last two it forms a white incrustation when these are dried, but in chesnuts, when produced in warm regions. It exists in the nectaries of many flowers, and is collected by the bees; hence honey is only one of the kinds of this sugar. Though harmless in probably all instances to the bees, from whatever plant collected, it not unfrequently has a poisonous influence over human beings, when it has been collected from poisonous plants, such as Rhododendrons and their allied genera.

Granular sugar is readily formed by the action of dilute sulphuric acid on starch, or sugar of milk, or the *bastard* sugar which remains after the finest refined sugar has been procured from the cane or beet-root sugar. Lignin, or anything containing or formed from it, such as saw-dust, linen-rags, or paper, may be likewise transformed into granular sugar. It is likewise the kind of sugar formed during the germination of seeds. Lastly, it is that kind of sugar which is formed by a perverted action of the digestive and assimilating organs in the disease termed *diabetes mellitus*. [DIABETES.] All these varieties taste less sweet than the cane-sugar, and also differ among themselves; thus grape and honey sugar are sweeter than that from starch, while starch sugar is sweeter than that obtained from juniper berries. All of them contain less carbon and more water than the cane sugar, and may be regarded as hydrates of sugar.

Sugar, which, though with difficulty crystallised, is referred to this section, exists in many fungi or mushrooms, especially of the genus Agaricus. While it contributes to their nutritive properties, it most likely proves one source of the poisonous qualities they sometimes possess, as it is occasionally transformed into oxalic acid. Masses of crystals have been observed on the cap of a mushroom, some of which were sugar, while others were oxalic acid. Free oxalic acid is found in the *Polyporus sulphureus*, Bull., which is most likely formed at the expense of the sugar.

The only uncrystallisable sugar which is capable of fermentation is the syrup which remains after the refining of the cane and other sugars. It receives the name of molasses, and is used in medicine under the name of Sacchari faex, which is preferable to that of *theriaca*, as this might lead to confusion with a poisonous compound which bears a similar name. Molasses are largely employed for the distillation of rum.

The kinds of sugar unsusceptible of fermentation are, the sugar of milk and mannite; yet sugar of milk, when by the action of dilute sulphuric acid it is converted into granular sugar, is as susceptible of fermentation as any of the above-described. In other respects it conducts itself like common sugar, except that with nitric acid, besides oxalic acid, it forms saclactic acid. It is procured from whey, either simply by evaporating to dryness (*saccharum lactis inspissatum*), or by crystallising it. It is frequently separated from the curd by the addition of a great many substances, which can coagulate this, such as alum, vinegar, tamarinds, and mustard, and in certain diseases these medicated wheys are much recommended.

Sugar of milk has little sweetness, but a hot solution of it tastes much sweeter than the dry sugar. Sugar of milk is much used by the followers of homœopathy as the material of their dynamised globules.

Manna sugar constitutes the greater portion of the manna which flows from the *Ornus europaea* and other ashes in the south of Europe, the bark of the olive-tree, many species of pines, the root and leaves of celery, the bulb of the common onion, and in the rhizome of the *Triticum repens*, or couch-grass. The sweet juices of many plants, such as beet, carrots, &c., when long exposed to the air, generate manna sugar by a partial fermentation. To prevent this is one of the great objects in the manufacture of beet-root sugar; hence the necessity for speedily concentrating and purifying this juice. To this variety of sugar probably belongs Cynodon, which exists in the root of *Digitaria* (*Cynodon*) *Dactylon*. And also the principle called *canellin*, obtained from *canella alba*.

The principle called glycyrrhizin, obtained from the liquorice-plants, and the analogous principle from the leaves of the abrus precatorius, and the root of the common polypody fern, probably belong here, as well as sarcocollin, which exists both in *Penæa mucronata*, *P. Sarcocolla*, and in the polypody. Picromel, or the sweet principle which exists in the bile of mammals and birds, is probably a variety of sugar, though unsusceptible of fermentation, and ought to be considered in conjunction with it, from the share it may have in augmenting the sugar in diabetes. (See Experiments of Claude Bernard.)

In treating of the dietetical properties of sugar, it is necessary to view it in a variety of conditions. In temperate climates sugar is regarded as a luxury, one indeed which is nearly indispensable; but in tropical countries it is a universal article of subsistence, partly as real sugar, and partly, and more generally, as it occurs in the cane, which is either simply chewed or sucked, or softened by previous boiling. In this state it is eminently nutritious. It has been called "the most perfect alimentary substance in nature," and the results, in the appearance of the negroes, during the cane harvest, notwithstanding the increased severe toils of that season, seem to confirm the statement. They almost invariably become plump and sleek, and scarcely take any other food while the harvest lasts; even the sickly revive, and often recover their health. The crude plant, or the newly expressed juice, contains water, sugar, gum, green fecula, extractive, gluten, acetic and malic acids, acetates of lime and potash, supermalate and sulphate of lime, and lignin. It is the object of the various processes to which the juice is subjected, both in the countries where it is produced and where it is refined, to separate the sugar from the other ingredients, some of which dispose it to ferment and spoil, and others are obstacles to its crystallising. (See a valuable paper by Messrs. Guynne and Young, in 'British Annals of Medicine,' vol. i., p. 778; and ii., p. 42, where they enumerate tannic acid and oxide of iron among the ingredients of raw sugar). By the removal of such of these principles as contain azote, especially the gluten and green fecula, the nutritive power of sugar is sensibly diminished.

However harmless the use of saccharine vegetables may be to persons in health, there cannot be a doubt but that in some instances they are extremely hurtful. "The derangement or partial suspension of the converting the saccharine principle in man into the albuminous or oleaginous, not only constitutes a formidable species of dyspepsia, but the unassimilated saccharine matter in passing through the kidneys gives occasion to the disease termed *diabetes*." The blood of a perfectly healthy individual contains no appreciable quantity of sugar; but in diabetes, sugar has been repeatedly ascertained to exist in the sanguiferous system,—a fact unequivocally demonstrating that the assimilating organs had failed to convert the saccharine aliment into the constituent principles of the blood. Oxalic acid is neither found in the blood nor in the urine in a state of health; but in certain forms of disease probably exists in both fluids. Lactic acid, when in excess, which forms one of the most troublesome kinds of acidity in the stomach, and the frequent concomitant of *bilious attacks*, is likewise the result of such mal-assimilation generally of the saccharine matter, though occasionally of albuminous matters. The prohibition of articles of a decidedly saccharine nature from the diet of diabetic patients becomes absolutely necessary. Not only sugar in its crystallisable states must be prohibited, but those fruits which contain it. A single peach or pear has occasionally brought back the disease in all its severity. Even those starchy or farinaceous matters which we have seen to be convertible into sugar must be avoided, especially potatoes, the starch of which is, of all others, the most easily transmuted into sugar which is of the same nature as the diabetic sugar.

The abuse of sugar is to be avoided by persons disposed to the oxalic acid diathesis; and persons of a bilious habit should use it with great moderation, as also those with tendency to rheumatism. (See Prout.)

Sugar, though prone to fermentation when in a dilute state, possesses when concentrated great antiseptic properties, and is extensively employed to preserve both animal and vegetable substances from decomposition. Sometimes the sugar existing naturally in many fruits is sufficient to ensure their preservation, as in figs, raisins, and other dried fruits; especially if the season has been bright and warm, when more sugar is elaborated. In other cases sugar is added, as in many preserves and jellies. Sugar added to meat, fish, &c., renders less salt necessary for keeping them, and preserves more of the natural taste and flavour. Many medicinal substances, as well as flavours and colouring principles, are preserved by means of sugar. [SYRUPS.] Sugar, from the readiness with which it reduces to a metallic state those bases which have a weak attraction for oxygen, has been proposed as an antidote in cases of poisoning with copper, corrosive sublimate, &c. It is to be doubted whether syrup is adequate to effect the reduction at the temperature of the stomach. On the other hand, sugar yields oxygen to those substances which attract it strongly, such as phosphorus; hence nothing so quickly and certainly revives a fire nearly extinct as throwing a little brown sugar on the embers. Sugar burnt at a low temperature constitutes *caramel;* one part of this dissolved in four parts of water constitutes the liquor (improperly called *tinctura*) sacchari tosti, which is employed as a colouring-matter for many liquids, especially for the dark-coloured sherries and other wines.

Refined sugar is much employed for the administration of volatile oils, constituting oleo-saccharums. Finely powdered white sugar sprinkled upon ulcers with unhealthy granulations acts as an escharotic.

The term sugar has been applied to some substances on account of their sweet taste, which are widely different from real sugar, and possess even poisonous properties, such as acetate of lead, or *sugar of lead*. Oxalic acid, another very poisonous substance, is often called, from being prepared from sugar, *acid of sugar*, and therefore thought to be harmless. Fatal accidents frequently result from this mistake. [OXALIC ACID.]

SUICIDE is the term usually applied both to the act of self-destruction and to him who commits it. As a subject of medical investigation, the most important distinctions among cases of suicide are founded on the circumstances which lead to its commission; and of these there are two chief classes: in one, a man is led to disregard his life for the sake of something for which his death is necessary; in the other, he is depressed by an evil more intolerable than the act of dying. But whichever of these be the motive, it may act in two different ways, and the suicide may be, as M. Esquirol has said, either acute and involuntary, or chronic and prepense. Or, again, suicides of all kinds may be divided (and this is probably the most practical method) according to the condition of the mind which has preceded the act, and which in each case constitutes the disposition to self-destruction.

In many cases this disposition is only a part of the general perversion of the judgment in complete insanity: it thus exists in certain maniacs in combination with many other signs of a diseased mind. Some are merely melancholy; some are carried on by illusions which lead them, as if unintentionally, to suicide; some have sensations which they imagine may be cured by such violence as proves fatal; some are driven to the act by commands which they imagine they have received; some destroy themselves at the commencement of insanity, when they are conscious of the malady which threatens them; others, in their convalescence, in horror at the excesses which they have committed, or at the mere thought of having been deranged.

There are also cases of monomania in which almost the only indication of insanity is the desire for self-destruction, excited by an illusion respecting some melancholy event, or by some fancied command. A peculiar and very terrible variety of this monomania, is that in which the desire for destruction leads the patient to take the lives of others, against whom he bears no ill-will, before he attempts his own. Many instances of this homicidal monomania, as it is called, are recorded.

There are conditions of the mind which are not called insanity (in the ordinary acceptation of the term), but which do not less strongly predispose to suicide. Such is especially that named *ennui*, or *tædium vitæ*, for which, though it is thought by foreigners to be so common in England that Sauvages has called it "melancholia Anglica," we have in our language no term except the very inexpressive one, *spleen*. Many circumstances give rise to this state of mind; most commonly it is the consequence of a want of occupation, or of a sudden transition from a state of active exertion in business or in pleasure, to one of voluntary or compelled repose; or it results from the difficulty which those who have long lived in the excitement of frivolous pursuits find in maintaining it by new objects of desire.

The state of the hypochondriac, though of somewhat the same kind, is less dangerous. He is persuaded indeed that his sufferings are irremediable, and that death would be a great relief to him; he even often talks of committing suicide; but he is as irresolute in the use of the means of death as he is anxious in the use of those for prolonging life; and if he do at last, after repeated postponements, attempt to destroy himself, the attempt is generally, through want of determination, abortive, and he again sinks into the same despondency and inactivity.

In all these cases the suicide is of the chronic or prepense kind; and in all, the condition of mind which precedes it is connected with a perversion of the judgment so obvious, that no reasonable person could hesitate to regard it as insanity. Whatever ingenuity of plan may have been shown in the preparation for the act, very few persons would deny that, under similar external circumstances, it would not have been committed by a sane man; and this is true of the great majority of prepense suicides in the present day.

In the acute or involuntary suicides, the predisposing condition of the mind is the result of circumstances which act rapidly, and pervert a judgment which, before their occurrence, might be deemed sound. Suicides of this kind are probably less frequent than those of the preceding; but they are usually more shocking, and attract more attention; they are especially common in large towns, or wherever men pursue great objects at great hazards. For instance, a loss of money or of honour, the failure of an ambitious enterprise, jealousy, and many afflicting events, are enough at once to deprive a man of tender sensibility of the power of just reflection, and to make him think that death is not so bad as the misery which he must undergo. On the spur of the moment of anguish he destroys himself. Similar circumstances impel a man of colder temperament, or of a braver disposition, more slowly to the same end. The one may for a time endure passively his disgrace; the other may have courage at first to bear up against it; but at length the judgment is in both alike perverted, and the same state of mind is produced which urges others to immediate self-destruction.

Lastly, there are examples in which suicide is committed with perfect coolness, being adopted, after due deliberation, as the most judicious course which, in the circumstances of the case, and as far as the knowledge of the individual enabled him to judge, could be followed. Such are many of the cases in which men, finding themselves afflicted with incurable and painful diseases, have shortened that which they believed would be a miserable life; and of the same class are the suicides committed in accordance with national custom, or superstition, or from patriotic motives. The cases of this class are not proper subjects for medical consideration, for in these there is no disorder of the mind. The act is committed either without deliberation, in obedience to custom or authority; or, when deliberation is used, the conclusion is only the necessary result of the error in the premises.

Such are the states of mind which most commonly predispose to suicide, and the circumstances which produce them. The character of the act itself usually corresponds closely with that of the mind by which it is urged. By those who commit it after deliberation, the means employed are almost always successful; so they are when men who have endured affliction for some time, at last sink under it. But when suicide is attempted under the sudden impulse of the fear of disgrace, the endeavour is often abortive; the means chosen are insufficient, or they are awkwardly employed; and it deserves notice, that the attempt generally seems to be the acme of the frenzy; for if it be unsuccessful, it is very rarely repeated, and often he who has made it, in the next minute seeks assistance, and bitterly repents his folly.

It is a generally received opinion that cold foggy climates favour the development of the suicidal disposition; but in Holland, the climate of which is very similar to that of Great Britain, the proportion of suicides is lower than in any other countries with milder climates; and that many circumstances are capable of counterbalancing whatever influence climate may have, is proved by the number of suicides in the same country having varied considerably in different periods. It has also been shown that the number of suicides, in proportion to the population, is greater in France than in England. In the year 1858, in England and Wales the total number of suicides was 1257, of whom 921 were males, and 336 females, or 1·6 in 20,000 of the whole population, or 1 in 450 of the deaths.

In accordance with the same general opinion, it is commonly said that suicides are more frequent in the latter part of the autumn than in any other season; but statistical inquiries would seem to indicate that the kind of weather which is most favourable to the suicidal disposition is rather that of long-continued heat and drought. The tendency to suicide varies greatly among persons of different stations and occupations. In a letter from Mr. Farr to the registrar-general, this tendency was shown to be "least among persons who carry on occupations out of doors, and greatest among artisans who are weakly from birth, are confined in-doors, have their rest disturbed, or have little muscular exercise."

From what has been said of the variety of causes which may engender or encourage the disposition to suicide, it must be manifest that no general account can be given of the morbid conditions of the body, or of the brain, which accompany the mental disturbance. Many facts relating to this part of the subject have been related; but as yet they are unconnected by any generalisation. We may therefore proceed at once from the causes to the treatment of the suicidal disposition.

Here also what has been said of the one may serve for a guide to the knowledge of the other. With respect to the treatment of those among the insane who exhibit a tendency to self-destruction, there can be no other deviation from the ordinary treatment of insanity than that which consists in the careful removal from them of all means by which their intentions may be accomplished. Both for these and for those who show no other sign of insanity than their desire for death, the most successful remedy is the giving full occupation for the time; this is indeed essential to the safety of all who show any disposition to suicide. The occupation moreover should be one which will carry the mind as far as possible from the subjects on which it is morbidly sensitive, or on which it has been accustomed to dwell too intently. Above all, a person suspected of an intention to commit suicide, should be kept carefully from the contemplation of histories of self-destruction. Numerous instances have proved that the tendency to imitate the acts of others operates as forcibly in producing suicides as in encouraging the most trivial fashion. For all cases of imitative suicide there is a plain preventive means which should never be neglected, namely, the fear of being disgraced after death; and that this operates forcibly in deterring men from suicide, is a sufficient proof of the imprudence of the opinion which regards suicide as affording by itself sufficient evidence of the insanity and irresponsibility of those who commit it.

SUICIDE, in Law, is death caused by the act of the party dying.

A rescript of Hadrian expressly directed that those soldiers who, either from impatience of pain, from disgust of life, from disease, from madness, from dread of infamy or disgrace, had wounded themselves or otherwise attempted to put a period to their existence, should only be punished with ignominia ('Dig.,' 49, tit. 16, s. 6, 'De Re Militari'); but the attempt of a soldier at self-destruction on other grounds was a capital offence; and those who, being under prosecution for heinous offences, or being taken in the commission of a great crime, put an end to their existence from fear of punishment, forfeited all their property to the Fiscus. ('Dig.,' 48, tit. 21, s. 3.) Suicide was not uncommon among the Romans in the later republican period; and it became very common under the emperors, as we see from the examples in Tacitus, and in the younger Pliny, who mentions the case of Corellius Rufus ('Ep.,' i. 12), Silius Italicus (iii. 7), Arria (iii. 16), and the woman (vi. 24) who succeeded in persuading her husband, who was labouring under an incurable disease, to throw himself, tied to her, into a lake. [SILIUS ITALICUS, in BIOG. DIV.] Except in the cases mentioned in the two titles of the 'Digest' above cited, suicide was not forbidden by the Roman law; nor was it discountenanced by public opinion.

Suicide, by the law of England, is a crime attended by some of the consequences attached to felony. It is called, in law, though incorrectly, *felonia de se*. A *felon de se* then is a person who being of years of discretion and in his senses, destroys his own life, either intending to do so, or intending to do some other act of a character both unlawful and malicious; the legal effect of which is a forfeiture to the crown of all the personal property which the party had at the time he committed the act by which the death was caused, including debts due to him. Though the crime is called felony, it was never attended with forfeiture of freehold, and never worked any corruption of blood. But formerly the crown was entitled to the year, day, and waste of the freehold lands of a self-felon; as we find that in 1289 the widow of Aubrey or Albert (Alberici) de Wytelesbury gave 300*l.* to the king (Edw. I.) to have all the goods and chattels of her husband, "a felon by drowning himself," saving to the king the year, day, and waste of Aubrey's lands and tenements. (2 Madox, 'Exch.,' 347.)

The fact that a self-felony has been committed is ascertained by an inquest or inquisition taken before the coroner or other officer having authority to hold inquests, upon view of the dead body, and examination of witnesses in the presence of a jury, summoned, as in other cases, to inquire into the cause of a sudden or violent death. [CORONER.]

Where a self-felony is found by the inquisition, the jury ought also to inquire and find whether the party had any, and, if any, what goods and chattels at the time when the felony was committed. But an omission in this respect may be supplied by an inquisition taken by the sheriff under a writ De melius inquirendo, or "further inquiry." The property in the self-felon's goods, upon being found in either of these modes, is vested in the crown with relation to the time of the felony, so as to make any intermediate dealing with the property void as against the crown.

The crown takes the property of the felon subject to no liability in respect of his debts or engagements. But upon a memorial presented to the treasury by a creditor, a warrant is generally obtained, authorising the grant of letters of administration to such creditor, who, upon such grant being made, acquires the ordinary rights, and becomes subject to the ordinary liabilities of a personal representative.

It was formerly usual for the crown to make grants to its servants and favourites of the property arising from these and other forfeitures. These grants were either of particular forfeitures, or of forfeitures accruing within a particular district. Grants of the latter description were usually made in fee simple, and many such grants are still in force in various parts of England.

The finding of the jury is not conclusive either as to the fact of self-felony or as to the property of the deceased; and all persons interested in controverting any part of the finding may plead to the inquisition, and contest its insufficiency by a demurrer, or deny its truth by a traverse. The issues, of law or of fact, raised upon such pleadings, are disposed of as in other cases. Formerly coroners returned their inquests into the court of King's Bench, in order that process might issue against those who made seizures, set up claims, or withheld property or debts in derogation of the rights of the crown. But since the 4 & 5 Will. and Mary, c. 22, that practice has been discontinued; and the course now is, for any party who considers himself aggrieved by the finding of the coroner's jury, to remove the inquisition by Certiorari into the court of Queen's Bench, when if in consequence of some legal defect the inquisition cannot be supported, the court will quash it without putting the party to the expense of a demurrer. If however the inquisition be good in substance, the coroner may be ordered to amend defects in form.

Neither self-felony nor any other crime can be committed by a child who has not attained years of discretion; nor can it be committed by a person who, by disease or otherwise, has lost, or has been prevented from acquiring, the faculty of discerning right from wrong. A tendency to self-destruction is common in several species of insanity, and the connection between the morbid affection and the act of violence which occasions death may often be very distinctly traced. It not unfrequently happens however that cases arise in which it is nearly impossible to determine whether the act is to be ascribed to a diseased state of the mental faculties, or to passions which are not under the ordinary restraint.

At common law, which in this respect follows the canon law, a person found by inquest to be felo de se is considered as having died in mortal sin; and his remains were formerly interred in the public highway without the rights of Christian burial, and a stake was driven through the body: but by the 4 Geo. IV., c. 52, the coroner or other officer by whom the inquest is held is required to give directions for the private interment of the remains of any person against whom a finding of felo de se shall be had, without any stake being driven through the body, in the churchyard or other burial-ground of the parish in which the remains of such person might by the laws or customs of England be interred, if the verdict of felo de se had not been found; such interment to be made within twenty-four hours from the finding of the inquisition, and to take place within the hours of nine and twelve at night, without performance of any of the rites of Christian burial.

The Code Pénal of France contains no legislation on the subject of suicide. Of the modern codes of Germany, some adopt the silence of the French code, and others vary in their particular provisions. In the Bavarian and Saxon codes suicide is not mentioned. The Prussian code forbids all mutilation of the dead body of a self-murderer under ordinary circumstances; but declares that it shall be buried without any marks of respect otherwise suitable to the rank of the deceased; and it directs that if any sentence has been pronounced, it shall, as far as it is feasible, be executed, due regard being had to decency and propriety, on the dead body. Besides which, the body of a criminal who commits self-murder to escape the execution of a sentence pronounced against him is to be buried at night by the common executioner, at the usual place of execution for criminals. The Austrian code simply provides that the body of a self-murderer shall be buried by the officers of justice, but not in a churchyard or other place of common interment.

SUIT is a legal term used in different senses. The word *secta*, which is the Latin form, is from "sequor," to follow; and hence the general meaning of the word may be deduced.

1. A suit is a proceeding by which any legal or equitable right is enforced in a court of justice. Where the remedy is sought in a court of law, the term is synonymous with action; when the proceeding is in equity, the term suit is alone used. It is also applied to proceedings in the ecclesiastical and admiralty courts.

2. Suit of court, in the sense of an obligation to follow, that is, to attend, and to assist in constituting a court, is either real or personal.

Suit-real, or rather suit regal, is the obligation under which all the residents within a leet or town are bound to attend the king's criminal court for the district, whether held before the king's officer and called the sheriff's tourn, or held before the grantees of leets or the officers of such grantees, and called courts-leet. [LEET.]

Suit-personal is an obligation to attend the civil courts of the lord under whom the suitor holds lands or tenements; as in manors [MANORS] where there are copyhold, that is, customary estates, the custom imposes upon the copyholder an obligation to attend the lord's customary court. In the case of freeholders attending as suitors the county court or the court-baron (as in the case of the ancient tenants per baroniam attending parliament), the suitors are the judges of the court, and the sheriff in the county court, the lord or steward in the court-baron, only presiding officers with no judicial authority. But in the criminal jurisdiction of the tourn and leet, the sheriff and the grantee of the leet, or his steward, are the judges; and the suitors act only a subordinate part.

3. Besides suit of court, secta ad curiam, there are other species of personal suit, which, like suit of court, are divisible into suit-service and suit-custom. Of these the most usual is suit of mill, secta ad molendinum, which is where, by tenure or by custom, the freehold or customary tenant is bound to grind his corn at the lord's mill.

SUIT AND SERVICE. [Suit.]

SULPH, or SULPHO. A prefix used in chemistry in naming a large number of substances containing the element sulphur. Most of these bodies will be found described under their respective names; but others will be found under the name to which the prefix is added, thus sulpholeic acid is described under Oleic Acid.

SULPHACETIC ACID $(C_4H_4S_2O_{10})$. An organic acid formed by the action of anhydrous sulphuric acid upon monohydrated acetic acid. It crystallises in very deliquescent needles. It is bibasic.

SULPHAMETHYLANE. [Methyl, *sulphamate of.*]

SULPHAMYLIC ACID. [Amyl.]

SULPHANILIC ACID $(C_{12}H_7NS_2O_6)$. An unimportant derivative of aniline.

SULPHANISOLIC ACID. A synonyme of methylsulphophenic acid. [Methyl; Phenylic Group.]

SULPHANISOLIDE. [Phenylic Group.]

SULPHATAMMON. [Sulphur.]

SULPHATES. [Sulphur, *Sulphuric Acid.*]

SULPHETHAMIC ACID $(C_{16}H_{23}NS_4O_{16})$. An ammoniacal derivative of sulphate of ethyl. In its most concentrated form it is a liquid. Ebullition decomposes it.

SULPHETHYLIC ACID. [Ethyl.]

SULPHETHYLOLIC ACID. Synonymous with ethylsulphurous acid. [Ethyl.]

SULPHIDES. [Sulphur.]

SULPHINDIGOTIC ACID. [Indigo.]

SULPHINDYLIC ACID. [Indigo.]

SULPHION. [Sulphur.]

SULPHISATANOUS ACID $(C_{16}H_{11}NO_4; S_2O_4)$. A crystalline acid of no importance derived from indigo.

SULPHISATHYD. [Indigo.]

SULPHITES. [Sulphur, *Sulphurous Acid.*]

SULPHOAMIDONIC ACID. [Sugar.]

SUPHOBENZIDIC ACID. [Phenyl-sulphurous Acid.]

SULPHOBENZIDE. [Phenylic Group.]

SULPHOBENZOENIC ACID. [Toluenic Group.]

SULPHOBENZOL $(C_{14}H_6S_2)$. A white crystalline organic substance isomeric with hydride of sulphobenzöyl. It is obtained by acting upon hydride of chlorobenzöyl with sulph-hydrate of potash.

SULPHOCARBONIC ACID. [Sulphur.]

SULPHOCARBONIC ETHER. [Ethyl.]

SULPHOCARBOMETHYLIC ACID. A synonyme of methyldisulphocarbonic acid. [Methyl.]

SULPHOCETIC ACID. [Cetyl, *Cetyl-sulphuric Acid.*]

SULPHOCHOLEIC ACID. [Choleic Acid.]

SULPHOCYANHYDRIC ETHER. [Ethyl.]

SULPHOCYANOGEN. [Cyanogen, *Cyanogen and Sulphur.*]

SULPHOFORM. [Methyl.]

SULPHOFLAVIC ACID. [Indigo.]

SULPHOFULVIC ACID. [Indigo.]

SULPHOFURETHANE. [Carbamic Acid.]

SULPHOGLUCIC ACID. [Sugar.]

SULPHOGLUTINIC ACID. [Naphthalic Group.]

SULPHOHAMATHIONIC ACID. An acid of problematical existence, said to be derived from Purree, or Indian Yellow.

SULPHOLIGNIC ACID. [Sugar.]

SULPHOMESITYLIC ACID $(C_{18}H_{12}S_2O_6)$. A crystalline acid produced by dissolving mesitylene in fuming sulphuric acid.

SULPHOMETHYLIC ACID. A synonyme of methyl-sulphuric acid. [Methyl.]

SULPHOMETHYLSULPHURIC ACID. A synonyme of methyl-sulphurous acid. [Methyl.]

SULPHOMOLYBDIC ACID. [Molybdenum, *sulphides of.*]

SULPHOMORPHIDE. [Opium, Alkaloids of.]

SULPHONAPHTHALIDAMIC ACID. [Naphthalic Group.]

SULPHONAPHTHALIDE $(C_{24}H_{10}SO_2?)$. A derivative of naphthalin is said to possess this formula, but it is probably a mixture of naphthalin and sulphonaphthalin.

SULPHONAPHTHALIN. [Naphthalic Group.]

SULPHONARCOTIDE. [Opium, Alkaloids of.]

SULPHOPHENIC ACID. [Phenylic Group.]

SULPHOPHENICIC ACID. [Indigo.]

SULPHOPHENYLAMIDE. [Phenylic Group.]

SULPHOPHENYLIC ACID. [Phenyl-sulphuric Acid.]

SULPHOPINIC ACID. [Opium, Alkaloids of.]

SULPHOPURPURIC ACID. [Indigo.]

SULPHORUFIC ACID. [Indigo; Salicylic Group.]

SULPHO-SALTS, or SULPHUR-SALTS. [Salts.]

SULPHOSINAPIC ACID $(C_8H_7NS_4)$. *Allyl-sulphocarbamic Acid.* An organic acid produced by the action of an alcoholic solution of potash upon sulphocyanide of allyl. The potash salt of the acid is thus obtained; the acid itself has not been isolated.

SULPHOSINAPISINE. [Sinapine.]

SULPHOTOLUENIC ACID. [Toluenic Group.]

SULPHOVINIC ACID. *Ethylsulphuric Acid* [Ethyl.]

SULPHOVIRIDIC ACID. [Indigo.]

SULPHOURETHANE. [Carbamic Acid.]

SULPHUR (S); commonly called *brimstone,* is a solid elementary non-metallic body, which has been known from the most remote antiquity. The former term is derived from *sal* salt, and *πῦρ* fire; the latter *brennestone* or *burnstone,* both in allusion to its well-known property of ready inflammability. It is met with in the pure state and in various forms of combination: thus it is found combined with numerous metals and in immense quantity with iron, forming the sulphide and bisulphide; with copper, lead, antimony, &c., constituting the principal ores of these metals: it is also found largely combined with oxygen, forming sulphuric acid, which is generally united with an earthy base, as with lime, constituting sulphate of lime, or gypsum; and with baryta, strontia, and magnesia, giving rise to the sulphates of those bases. It occurs also, but in smaller quantity,—and principally in mineral waters, such as those of Harrowgate,—combined with hydrogen, the compound being sulphuretted hydrogen gas, or hydrosulphuric acid. Sulphur is a constituent of some animal substances, as albumen, urine, &c. It is found also in certain plants: in the natural order *Liliaceæ,* as in garlic; *Cruciferæ,* as in mustard; and *Umbelliferæ,* as in *Asafœtida.*

The chief source of this element is *native sulphur,* the most remarkable deposits of which occur in Sicily, whence an immense quantity is imported into this country. It occurs also in the fissures of lava near the craters of volcanoes, in Italy, Guadaloupe, Nevis, Iceland, and the volcanoes of the Cordilleras. [Sulphur, in Nat. Hist. Div.]

Sulphur is separated from the grosser impurities by crude processes of fusion and distillation, performed soon after it is collected. That sent to Great Britain is, however, finally purified in this country, and has different forms given to it according to circumstances. What is called *refined sulphur* is that purified by distillation in a large cast-iron still, and condensed in a receiver kept cool. When the vaporised sulphur is condensed in a large chamber, it has the form of powder, and is called *sublimed sulphur* or *flowers of sulphur;* but as the walls of the chamber get hot, the sulphur melts, collects on the floor, and is run off into wooden moulds, the product being *roll* or *stick sulphur.* The residue in the retort still contains sulphur, and, under, the name of *sulphur vivum* or *black sulphur,* is occasionally used as a cattle medicine and for dressing mouldy hops.

Precipitated sulphur or *milk of sulphur,* is a finely divided form of the element thrown down on adding a strong solution of polysulphide of calcium, sodium, or potassium to dilute hydrochloric acid; sulphuric acid is sometimes used instead of hydrochloric, sulphate of lime being thereby precipitated along with the sulphur, and the weight of the latter thus fraudulently increased. This adulteration may readily be detected on heating a little of the suspected specimen, when the sulphur being volatile will be expelled, and the sulphate of lime left behind. The microscope also will at once detect the falsification, for the sulphur has a fine granular appearance, while the gypsum is in well defined crystals.

Sulphur is sometimes prepared from iron pyrites (FeS_2), by distillation. One third of the sulphur present in the ore is volatilised and condensed in the usual way, while magnetic pyrites (Fe_3S_4) remains in the retort. Sulphide of copper is also a source of sulphur, the latter being a sort of bye-product, although an important one, in the preliminary roasting operations connected with copper smelting.

Sulphur has already been referred to [Allotropy] as existing in three allotropic states. The first form ($S\alpha$) is that of an octohedral crystal with a rhombic base, and is the condition in which it occurs in nature. It is artificially obtained in the same form, but more transparent on allowing its solution in chloride of sulphur or bisulphide of carbon to evaporate spontaneously; its specific gravity is 2·05, and it fuses at 239° Fahr. The second form ($S\beta$) occurs in transparent acicular crystals of dark yellow colour. To obtain it, a quantity of sulphur is melted and slowly cooled; when the outer portions have solidified, holes are made in the crust, and the still liquid sulphur in the interior is poured out; on breaking open the shell its inner surface will be found to contain the needles in question. They are not permanent, but soon change into the light yellow semi-opaque sulphur (α); the acicular form is, however, still retained, although each needle is a congeries of minute rhombic octohedra. Much heat is evolved during the transformation. The third state ($S\gamma$) is very peculiar, and is brought about as follows:—The fusing-point of sulphur is 239°, and between this and 280° it possesses the highest degree of fluidity: at 320° it begins to thicken, and at 482° is so tenacious, that it will scarcely flow from an inverted vessel; from this to 600°, which is its boiling-point, it again becomes liquid, but not so perfectly so as at 280°. If now it be poured into water it becomes a brown pasty mass, which readily receives and retains any form given to it, and hence is employed in taking casts. Magnus has shown that this deepening in colour is due to a fourth modification of sulphur, which is black; it is formed on many times repeating the process of heating a quantity of sulphur to 600° Fahr., and suddenly cooling in cold water.

Sulphur is insoluble in water, but dissolves in alcohol, if both substances are exposed to each other in the state of vapour: on the addition of water, the sulphur is precipitated. It is dissolved by boiling oil of turpentine; the solution has a reddish-brown colour, and, on cooling, minute crystals of sulphur are deposited. It is readily taken up by chloride of sulphur, and is soluble in about three times its weight of bisulphide of carbon; the elastic variety is, however, not so soluble. Sulphur is also soluble to a small extent in ether and in chloroform.

Sulphur is a bad conductor of heat; it is very volatile, and when it is rubbed in the dark on a brick, or any other substance by which it is heated, though not sufficiently to inflame it, an extremely weak blue flame arises, exhaling a peculiar odour; this flame is not, however, occasioned by combustion, it merely accompanies the evaporation of the sulphur, for a cold body held over it is covered with flowers of sulphur. When sulphur is heated, it begins to vaporise before it fuses; at 600° Fahr. it is rapidly volatilised, and in close vessels is condensed without change. The specific gravity of the vapour of sulphur is 6·617 at 900° Fahr., but at 1900° Fahr. it is 2·2. Its combining volume below 1500° Fahr. is ⅓, but at 1900° Fahr. it is 1. It unites directly with some metals to form *sulphides*.

When heated in the air sulphur quickly takes fire and burns with a pale blue flame, generating much heat.

The equivalent of sulphur is 16.

Compounds of Sulphur and Oxygen are seven in number, namely :—

		Sulphur per cent.	Oxygen per cent.
Sulphurous acid . . .	SO_2	50·00	50·00
Sulphuric acid	SO_3	40·00	60·00
Hyposulphurous acid . .	S_2O_2	66·66	33·34
Hyposulphuric acid . . .	S_2O_5	44·45	55·55
Trithionic acid . . .	S_3O_5	54·55	45·45
Tetrathionic acid . . .	S_4O_5	61·53	38·47
Pentathionic acid . . .	S_5O_5	66·66	33·34

Sulphurous acid (SO_2) *Sulphurous anhydride.*—This gas escapes, in the gaseous state, from fissures in the ground in the neighbourhood of volcanoes. It is artificially obtained in the pure state on heating about two parts of mercury with three of strong sulphuric acid :—

$$\underbrace{Hg}_{\text{Mercury.}} + \underbrace{4(HO, SO_3)}_{\text{Sulphuric acid.}} = \underbrace{HgO_2, 2SO_3}_{\text{Bisulphate of mercury.}} + \underbrace{4HO}_{\text{Water.}} + \underbrace{2SO_2}_{\text{Sulphurous acid.}}$$

Copper clippings may be economically substituted for mercury, but as met with in commerce they generally contain matters that affect the purity of the gas. On the large scale, solution of sulphurous acid is preferable to the gas itself, and is manufactured directly from sulphur. The latter is burnt in a furnace, and the sulphurous acid produced cooled by passing through earthenware tubes surrounded by cold water. It is then made to ascend through a tall and wide wooden column packed with pumice-stone that has been digested in hydrochloric acid and well washed. In ascending the sulphurous acid meets with a stream of water, the flow of which is so regulated that a saturated solution shall flow off at the bottom of the column. It is stored for use in a closed reservoir.

Sulphurous acid gas is colourless, and permanently elastic; that is, not condensed into a fluid or solid by exposure to common degrees of cold under the ordinary pressure. It condenses to the liquid state, however, on being passed through a tube surrounded by a freezing mixture of ice and salt. In this condition it may be preserved in hermetically sealed tubes, on the interior of which, at 60° Fahr., it exerts a pressure of two and a half atmospheres. At —105° Fahr. it freezes to a colourless, transparent, crystalline solid.

Sulphurous acid gas has a pungent and suffocating odour, being that experienced whenever sulphur is burned; its taste is disagreeable and acid; it extinguishes burning bodies, is not inflammable, and is fatal to animals. Water at 60° Fahr. dissolves from 33 to 37 times its volume of this gas; by heating the solution it is evolved unaltered. The solution possesses the smell of the gas itself; and, like it, has the property of bleaching some vegetable and animal substances: hence the employment of the vapour of burning sulphur in whitening hops, silk, wool, and straw.

One hundred cubic inches of sulphurous acid gas weigh 68·8 grains; its density therefore is about 2·22. Being so much heavier than air it may be collected in vessels by displacement. [Gases, Collection of.]

The aqueous solution of sulphurous acid, when exposed to oxygen, slowly combines with it, and the result is sulphuric acid; but unless moisture be present, no combination takes place between these two gases.

Sulphurous acid combines with various bases to form salts, which are called *sulphites*. When, for example, this gas is passed into an aqueous solution of ammonia, they readily combine, and the resulting salt is sulphite of ammonia, which may be obtained in prismatic crystals. It is very soluble in water, and produces much cold during solution; by exposure to the air it attracts oxygen, and becomes sulphate of ammonia. When, however, dry sulphurous acid gas and dry ammoniacal gas are brought into contact, deep yellow-coloured crystals are formed, which have been termed *sulphitammon*, or improperly *sulfamide;* they contain the elements of sulphurous acid and ammonia combined, but in a different mode to that which forms anhydrous sulphite of ammonia. By exposure to the air sulfamide becomes white, deliquesces, and gradually becomes sulphate and hyposulphate of ammonia.

The alkalies potash and soda, the alkaline earths, and several metallic oxides, may be combined with sulphurous acid, and they form *sulphites;* but these compounds are not of much importance, except perhaps that of soda. [Sodium, *sulphite of.*] In contact with air they are slowly converted into sulphates.

Sulphuric Acid (HO, SO_3).—This acid has been long known, and is very extensively employed, 100,000 tons being annually consumed in Great Britain alone. When combined with water, in which state it is best known, it was originally, and still is frequently, called *oil of vitriol:* first, because it is an oily looking liquid; and secondly, on account of its being obtained from green vitriol, or copperas, now called sulphate of iron.

The process just alluded to was first followed at Nordhausen in Germany, and the peculiar compound of sulphuric acid and water produced by it is still called Nordhausen oil of vitriol, to distinguish it from common oil of vitriol, a different compound as regards the water which they contain, and obtained by a different process. We shall first describe the original process and product.

Iron pyrites is a well known and very abundant natural substance: it is correctly termed *bisulphide* of iron, and consists of two equivalents of sulphur and one equivalent of iron. When certain varieties of this compound are exposed to air and moisture, both the sulphur and iron are oxidised at the expense of the oxygen of the air; and though sulphur by itself is incapable of undergoing this change, yet, when combined with iron, it acquires from the air sufficient oxygen to become sulphuric acid, and the iron attracts enough to become protoxide; and these combining together, and with water, constitute the well-known crystalline body, hydrated sulphate of protoxide of iron, usually called, for brevity's sake, merely sulphate of iron, and originally green vitriol. This consists of one equivalent of sulphuric acid, one of protoxide of iron, and seven equivalents of water. Sulphuric acid consists of three equivalents of oxygen and one equivalent of sulphur. In order to procure the acid from it, the salt is moderately heated, so as to expel the greater part of the water: in this state it is put into earthen retorts, and subjected to a very high temperature, during which there comes over and condenses in the receiver a dark-coloured dense fluid, which is the Nordhausen oil of vitriol; the cause of the colour has not been ascertained, but it appears to be an accidental and not a necessary accompaniment. This liquid emits a white vapour when exposed to the air, and hence it is called *fuming sulphuric acid.* It is composed of two equivalents of sulphuric acid and one equivalent of water ($HO, 2SO_3$).

Now it happens that anhydrous sulphuric acid is more volatile than that combined with water, so that when the above acid is heated in a retort, there first comes over and condenses in the receiver anhydrous sulphuric acid, and there remains in the retort hydrated sulphuric acid.

We shall first and briefly state the properties of the anhydrous acid. It is a colourless crystalline solid, is tough and elastic, liquefies at 66°, and boils at a temperature between 104° and 122°, forming a transparent vapour, provided no water is present; it unites with moisture when exposed to the air, and forms with it dense white fumes. It is sometimes prepared as a matter of curiosity, but is hardly applied to any use. Though called an acid, it in reality possesses no acid properties, and may be moulded in the fingers, like wax, without injuring the skin. When thrown into water it hisses as red-hot iron would do, and then has the usual powerful properties of common hydrated sulphuric acid.

The hydrated sulphuric acid, commonly called oil of vitriol, or simply sulphuric acid, is the compound which is so largely employed in numerous chemical operations and manufactures. It is, however, and has indeed for many years been, prepared in a much preferable mode to that described by the decomposition of sulphate of iron. The process consists in oxidising sulphurous acid through the agency of nitrous acid.

First, nitrate of potash or soda is decomposed by the addition of sulphuric acid, in the same mode as that employed for preparing nitric acid.

Sulphur is then burned in a furnace so contrived that the current of air which supports the combustion conducts the gaseous products, including the nitric acid fumes and excess of air, into large leaden chambers, the bottoms of which are covered to the depth of a few inches with water. The nitric acid of the nitre, composed of oxygen and nitrogen, is here decomposed, yields oxygen to a portion of the sulphurous acid formed by combustion, and converts it into sulphuric acid. The nitric acid, on losing oxygen, is converted into nitric oxide, which, by mixing with the air at the moment of its separation, combines with its oxygen, and gives rise to red nitrous acid vapour. The gaseous substances present in the leaden chambers are therefore sulphurous and nitrous acids, atmospheric air, and watery vapour. Now, when dry sulphurous acid gas and dry nitrous acid gas are mixed together, no action occurs between them; but when a little moisture is added, a white crystalline compound of sulphuric acid, hyponitrous acid, and water is formed; and when this falls into the water of the chamber, or comes into contact with steam, which is for this purpose blown into the chamber, it is instantly decomposed, the sulphuric acid is dissolved, and nitrous acid and nitric oxide gases escape with effervescence. The nitrous acid thus set free, as well as that reproduced by the nitric oxide uniting with the oxygen of the atmosphere, is again intermixed with sulphurous acid and moisture, and thus gives rise to a second portion of the crystalline body, which undergoes the same change as the first; and this operation is repeated until the water at the bottom of the lead-chambers is sufficiently acid to be removed for ulterior operations. The amount of nitric acid required in this operation is of course exceedingly small, inasmuch as the nitric oxide contained in it is not consumed, but acts only as a carrier of oxygen from the air to the sulphurous acid. Some nitric oxide is, however, conveyed out of the chambers by the escaping nitrogen of the air, and is in most works lost. A few manufacturers cause the escaping gases to pass over strong sulphuric acid that is trickling through a coke column, by which the nitric oxide is dissolved and subsequently recovered from the liquid by exposure to a stream of sulphurous acid in a second similar coke column.

It thus appears that sulphur during combustion can combine only with sufficient oxygen to become sulphurous acid; but what is curious is, that sulphurous acid becomes sulphuric acid by taking oxygen from nitrous acid, the nitric oxide of which appears nevertheless to have a stronger affinity for oxygen, since it can take that element rapidly from the air, which sulphurous acid cannot. The first attempt at explaining the mode in which nitric acid acts in this operation was made by MM. Clement and Desormes: it was subsequently further explained by Davy and other chemists.

Of late years also sulphuric acid has been made from iron pyrites, the sulphurous acid being formed by combustion, and converted into sulphuric by the agency of nitrous acid, in the manner already described.

When the sulphuric acid in the chambers has acquired a density of about 1·6, it is drawn off and further concentrated in open leaden vessels by heat; after this it is again removed either to glass or platina retorts, and heated till it has acquired a density of about 1·846. This is then the sulphuric acid, or oil of vitriol, of commerce, composed of one equivalent of sulphuric acid and one equivalent of water (HO, SO_3).

This acid is a limpid, inodorous, colourless fluid, of an oily consistence. It boils at about 620°, and distils over unchanged; the boiling-point diminishes with dilution: thus, when of specific gravity 1·78 it boils at 435°, and when 1·65 only at 350°, the concentrated acid freezes at −15°, but when it contains two equivalents of water instead of only one, and has a specific gravity of 1·78, it freezes at −40°.

Sulphuric acid is intensely caustic and acrid, and readily decomposes animal and vegetable fibre; even when diluted to a very great extent it has an extremely sour taste, and turns vegetable blues strongly red: on the other hand, when concentrated, it turns turmeric-paper of a brownish colour, as the alkalies do; but the effect is not permanent, for it is removed by water. Its affinity for water is very great, attracting it so readily from the air that in moist weather three parts increase to four in 24 hours, and by longer exposure the quantity is increased. When suddenly mixed with water, much heat is evolved, and, on cooling, condensation is found to have taken place, the two fluids occupying less space than before mixture. When sulphuric acid is mixed in certain proportions with snow, heat is given out, or cold generated, according to the quantities employed: thus four parts of acid and one of snow evolve heat, but four of snow and one of acid occasion cold.

Sulphuric acid is employed for a vast number of purposes: thus, on account of its great chemical power, it is used for the purpose of separating other acids from bases, as in preparing nitric, hydrochloric, acetic, phosphoric, and carbonic acids, &c. It is also used in preparing sulphates, a class of salts we shall presently again refer to. Perhaps the greatest consumption of sulphuric acid is in the decomposition of salt at alkali works where carbonate of soda is manufactured.

The strength of sulphuric acid is readily ascertained by taking its specific gravity and referring to such a table as the following, constructed by Ure:—

Specific gravity.	SO_3 in 100 parts.	Percentage of HO, SO_3.	Specific gravity.	SO_3 in 100 parts.	Percentage of HO, SO_3.
1·8460	81·54	100	1·6415	60·34	74

The salts which sulphuric acid forms with various bases are termed *sulphates*, *sesqui-sulphates*, or *bi-sulphates*, &c., according to circumstances. They are a very important class of saline bodies, and those of most use will be found described under their respective bases. With sulphuric anhydride, dry ammoniacal gas forms large transparent crystals, containing NH_3, SO_3, and termed *sulphatammon;* by long boiling with water, it is converted into sulphate of ammonia (NH_4O, SO_3).

According to the binary theory of the constitution of salts, sulphates are not combinations of the basic oxide and sulphuric acid, but of a hypothetical body, *sulphion* (SO_4), with the metal, or radical, of the base: thus, sulphate of soda (NaO, SO_3) is *sulphionide of sodium* (Na, SO_4), and sulphuric acid (H, SO_4) *sulphionide of hydrogen.* There are, however, several objections to this view of the constitution of sulphates.

Sulphuric acid in its concentrated state, and at common temperatures, acts only slightly, if at all, on the metals; but when they are heated together, the acid is generally decomposed, sulphurous acid and a sulphate of metallic oxide being produced: thus, when copper is heated in concentrated sulphuric acid, the acid yields one of its three equivalents of oxygen to the copper, which becomes protoxide; while the sulphur combined with two equivalents of oxygen is given off in the state of sulphurous acid; and this, as already indicated, is one of the best methods of procuring sulphurous acid. When, on the other hand, sulphuric acid is diluted, it has no action, even when heated, on copper; but on zinc, iron, and such other metals as readily decompose water, it acts with great readiness: the metal, being oxidised by the oxygen of the decomposed water, is dissolved by the acid, while the hydrogen of the water is given out in the gaseous state; by this operation, then, we procure a metallic sulphate and hydrogen gas.

Sulphuric acid and all sulphates are decomposed by the salts of baryta and of lead, minute quantities either of the acid or soluble salts being rendered evident by the formation of a dense white precipitate either of sulphate of baryta or lead; 116·5 parts of the former or 115·6 parts of the latter sulphate, when dry, indicate 40 parts of anhydrous sulphuric acid.

Commercial sulphuric acid generally contains sulphate of lead derived from the vessels used in its manufacture; it is nearly all precipitated as a white powder on diluting the acid with water. It frequently also contains traces of arsenic derived from the pyrites; in this case, sulphuretted hydrogen gives a yellow precipitate when passed through the diluted acid, or the contamination may be detected by Marsh's test. Small quantities of nitric and sulphurous acids are also sometimes present in common sulphuric acid. If required to be purified and concentrated, it is boiled and distilled. As lead would melt at the heat here employed, and as most other common substances would be corroded, platinum is often employed as a material for the still, at a heavy expense. Glass is another material employed for sulphuric acid stills. When the acid has been condensed to a specific gravity nearly double that of water, it is ready for sale.

Hyposulphurous Acid (HO, S_2O_2). *Dithionous acid.* In 1817 Dr. Thomson inferred the existence of an acid of sulphur in the salts called *sulphuretted sulphites:* this acid and its compounds have been particularly examined by Sir John Herschel.

Hyposulphurous acid has not been obtained in a separate state, but its composition has been determined to be in accordance with the above formula.

This acid is procured by dissolving zinc or iron in close vessels in an aqueous solution of sulphurous acid: solution is effected in this acid without the evolution of any gas, which hardly happens in any other case: the metals thus dissolved form crystallisable salts, which, when decomposed by other acids, yield sulphurous acid and sulphur, previously existing in the proportions above stated, and constituting hyposulphurous acid: this acid is also formed when sulphites are digested in close vessels with sulphur, in which case the sulphur takes half the oxygen of the sulphurous acid; when iron is dissolved in sulphurous acid, it takes half the oxygen of the sulphurous acid, which, by this loss becomes hyposulphurous acid, and, combining with the oxide of iron formed, they constitute hyposulphite of iron.

Most of the salts containing hyposulphurous acid, or the hyposulphites, are unimportant; the acid undergoes decomposition when they are strongly heated or acted upon by an acid.

Hyposulphite of soda ($NaO, S_2O_2 + 5$ Aq.), in solution, is largely used in photography to "fix," or render permanently unalterable the photographic picture. This it does by dissolving the aqueously insoluble silver salts, with which it forms double compounds having an intensely sweet taste. Hyposulphite of soda is made by dissolving sulphur in sulphite of soda, $NaO, SO_2 + S$ becoming NaO, S_2O_2.

Hyposulphuric Acid (HOS_2O_5). *Dithionic Acid.* This acid was discovered in 1819 by Gay-Lussac and Welter. It is prepared by suspending finely-powdered binoxide of manganese in water, and passing sulphurous acid gas into the mixture: if this be not kept cold, sulphuric acid is formed: but otherwise the oxide of manganese is dissolved and hyposulphate of its protoxide formed: to the filtered solution sulphide of barium is to be added, by which sulphide of manganese is precipitated, and hyposulphate of baryta remains in solution: when the proper quantity of sulphuric acid is added to this, sulphate of baryta is precipitated, and the hyposulphuric acid is liberated, the filtered solution of which is to be evaporated in vacuo over sulphuric acid till it acquires a density of 1·347: if it be carried further than this, it is decomposed into sulphurous acid, which escapes, and sulphuric acid, which remains dissolved.

This acid has not been obtained free from water: the aqueous solution is sour, inodorous, and reddens vegetable blues: if heated to 212°, it is decomposed into sulphurous and sulphuric acids; and when exposed to the air, it slowly absorbs oxygen; and becomes sulphuric acid. Unlike sulphuric acid, it forms soluble compounds with lime, baryta, strontia, and oxide of lead; but, like diluted sulphuric acid, it acts upon and dissolves zinc, with the evolution of hydrogen gas, and a solution of hyposulphate of zinc is formed; its salts are decomposed at a high temperature, yielding sulphurous acid and sulphates remaining.

Trithionic acid (HO, S_3O_5). *Sulphuretted hyposulphuric acid.* As a potash salt this acid is formed when sulphur is digested in bisulphite of potash for several days, or until all yellow colour has disappeared. The resulting solution gives a black precipitate with subnitrate, and a white with pernitrate of mercury. From the trithionate of potash the acid may be liberated by tartaric acid, and obtained in unstable prismatic crystals by evaporation. By heat the trithionates split up into sulphur, sulphurous acid, and sulphate of the base.

Tetrathionic acid (HO, S_4O_5). *Bisulphuretted hyposulphuric acid.* Two equivalents of hyposulphite of baryta and one of iodine yield iodide of barium and tetrathionate of baryta. The latter may be purified by recrystallisation, and the acid liberated by the cautious addition of sulphuric acid. It is somewhat unstable.

Pentathionic acid (HO, S_5O_5). *Trisulphuretted hyposulphuric acid.* When sulphurous and hydrosulphuric acids come into contact, the following decomposition occurs:—

$$\underbrace{5SO_2}_{\text{Sulphurous acid.}} + \underbrace{5HS}_{\text{Hydrosulphuric acid.}} = \underbrace{HO, S_5O_5}_{\text{Pentathionic acid.}} + \underbrace{S_5}_{\text{Sulphur.}} + \underbrace{4HO}_{\text{Water.}}$$

Pentathionic acid is very unstable. Its baryta compound may be obtained in silky scales.

Chlorosulphuric acid or *chloride of sulphuryl* (SO_2Cl). A colourless liquid of pungent odour and powerful eye-irritating properties, formed on bringing together dry sulphurous acid and chlorine gases in bright sunlight. It is volatile without decomposition, but water instantly breaks it up. It does not appear to combine with bases.

Nitrosulphuric acid (HO, SO_2NO_2). If nitric oxide (NO_2) be passed through a cold solution of sulphite of ammonia containing large excess of ammonia, white crystals of *nitrosulphate of ammonia* (NH_4O, SO_2NO_2) are deposited. Other nitrosulphates may be formed, but they are very unstable, and the acid cannot be liberated from them.

Sulphazotised acids, discovered by Fremy, form with potash, but not with soda, a remarkable series of salts. They are derived from basic nitrite of potash, sulphurous acid and water, as indicated in the following equations:—

Sulphazite of potash . . . . $3KO, S_3NH_3O_{12}$
from $3KO, NO_3 + 3SO_2 + 3HO$.
Sulphazate of potash . . . . . $3KO, S_4NH_3O_{14}$
from $3KO, NO_3 + 4SO_2 + 3HO$.
Sulphazotate of potash . . . . $3KO, S_5NH_3O_{16}$
from $3KO, NO_3 + 5SO_2 + 3HO$.
Sulphammonate of potash . . . . $4KO, S_8NH_3O_{22}$
from $4KO, NO_3 + 8SO_2 + 3HO$.

Nitrogen and Sulphur. [NITROGEN.]

Hydrogen and Sulphur combine in two proportions, forming *hydrosulphuric acid* (HS), frequently called *sulphuretted hydrogen*, and persulphide of hydrogen (HS_2 ?).

Hydrosulphuric acid, formerly known by the name of hepatic gas, exists in sulphurous waters, such as those of Harrowgate. It may be formed, to a certain extent, by heating or subliming sulphur in hydrogen gas. It is usually produced by the action of hydrochloric acid on sulphide of antimony, or by acting upon protosulphide of iron with dilute sulphuric acid: in the former case the hydrogen of the hydrochloric acid unites with the sulphur of the sulphide, chloride of antimony being also formed; while in the latter, the decomposed water yields hydrogen to the sulphur and oxygen to the iron, which latter, being then dissolved by the acid, constitutes sulphate of iron. As it is difficult to combine the whole of any given quantity of iron with sulphur, the uncombined portion yields a little free hydrogen with the hydrosulphuric acid; but this, in most cases, is of no consequence. Although hydrosulphuric acid is soluble in one-fourth its bulk of water, yet the gas may for most purposes be received by displacement in vessels filled with that liquid.

Hydrosulphuric acid is colourless, and gaseous at common temperatures and pressures: it has a peculiarly nauseous and fetid odour, resembling that of putrid eggs; its taste is also extremely disagreeable. Its specific gravity is about 1·192. 100 cubic inches weigh about 38 grains. It is composed of one equivalent of hydrogen and one equivalent of sulphur, as indicated in the above formula. It reddens moist litmus-paper, but not strongly, and is soluble in about one-third of its bulk of water. At a temperature of 50°, and under a pressure of about 17 atmospheres, it is rendered a limpid liquid, of specific gravity about 0·9: this does not congeal till cooled down to 122° Fahr. It is extremely poisonous to animals: air containing 1-1500th of its bulk immediately killed a bird, and 1-1000th a middle-sized dog. When mixed and detonated with oxygen gas, the results are water and sulphurous acid.

The aqueous solution of hydrosulphuric acid is employed as a test of metals, and, more especially, for the discovery of minute portions of lead, with which it gives a dark-coloured precipitate of sulphide of lead: with the salts of antimony it gives an orange precipitate, and with arsenious acid a yellow one.

Hydrosulphuric acid forms salts which are termed *hydrosulphates*, and these are probably formed when it is combined with ammonia, potash, soda, and the alkaline earths; but by metallic oxides, properly so called, it is decomposed, the results not being hydrosulphates of metallic oxides, but water and a metallic sulphide: this is the case with oxide of lead, silver, &c.

Persulphide of Hydrogen (HS_5 ?). This compound cannot be formed by direct combination. To prepare it, equal weights of sulphur and recently slaked lime may be boiled in three times their weight of water for half an hour. The result is a deep reddish-yellow coloured solution of persulphide of calcium, which, when clear and cold, is to be added to an excess of hydrochloric acid diluted with about twice its weight of water: by their mutual action sulphur is precipitated, accompanied by a yellow oil-like fluid, which is the persulphide of hydrogen. It is a viscid liquid, of a yellow colour, and of specific gravity about 1·77; its smell is similar to, but not so powerful as that of hydrosulphuric acid; its elements are held together by a feeble affinity, so that even in the cold it is gradually converted into hydrosulphuric acid and sulphur, and this change is immediately produced at 212°.

Chlorine and Sulphur appear to form two compounds, the chloride and di-chloride. According to Dumas, when sulphur is acted upon by excess of chlorine, a *neutral chloride* is obtained, which consists of one equivalent of chlorine and one equivalent of sulphur (SCl).

It usually contains some di-chloride, from which it is to be purified by repeated distillation at about 140° Fahr.

It may be formed either by heating sulphur in excess of dry chlorine gas, or, at common temperatures, by passing excess of chlorine through a tube containing powdered sulphur.

Chloride of sulphur is liquid, has a reddish-brown tint, and a density of 1·62; that of its vapour being about 3·7. Its boiling-point is 147°.

Di-chloride of Sulphur (S_2Cl).—This substance was first obtained by Dr. Thomson. When chlorine gas is passed over powdered sulphur, gently heated, it gradually disappears, and the di-chloride is formed by direct combination: the liquor obtained is to be distilled, and then possesses the following properties:—It is liquid, and is red by reflected, and yellowish-green by transmitted light: it emits acrid fumes when exposed to the air; its density is 1·628, that of its vapour being 4·7; it is volatile below 200°, and boils at 280°. Dry litmus-paper is not altered by it. It is energetically decomposed by and decomposes water, the results being hydrochloric and hyposulphurous acids. It does not combine with alkalies.

Sulphur and Bromine. [BROMINE.]

Carbon and Sulphur.—These form by direct action *bi-sulphide of carbon* (CS_2) or *sulphocarbonic acid.*

It may be obtained either by passing the vapour of sulphur over charcoal heated to redness in a porcelain tube, or distilling a mixture of bi-sulphide of iron and one-sixth of its weight of charcoal. It may be condensed by being passed into cold water, and to free it from uncombined sulphur and moisture it should be rectified from chloride of calcium at a low temperature.

It is a colourless transparent liquid, of density 1·272, that of its vapour being 2·447; it has an acrid pungent taste, and a very fetid odour; its refractive power is very high; it is insoluble in water, but combines with alcohol and ether, from which water precipitates it; it is extremely volatile, boils at 118·5°, and is not rendered solid at the lowest obtainable temperature: owing to its great volatility, it produces sufficient cold under the exhausted receiver of the air-pump to freeze mercury: it is extremely inflammable, the results of its combustion being carbonic and sulphurous acid gases, attended with a brilliant greenish-white flame. It combines with metallic sulphides to form a class of sulphur salts termed *sulpho-carbonates;* for example, sulpho-carbonate of potassium (KS, CS_2).

It is a remarkable circumstance that so volatile a liquid should be produced by the combination of two solid bodies. It was discovered by Lampadius in 1796.

Phosphorus and Sulphur. [PHOSPHORUS.]

Iodine and Sulphur. [IODINE.]

Selenium and Sulphur. [SELENIUM.]

Boron and Sulphur. [BORON.]

Sulphur Salts.—These are certain double sulphides, so designated by Berzelius: the electro-negative sulphides constituting *sulphur acids;* and the electro-positive sulphides, *sulphur bases.* Among the sulphur acids are the sulphides of arsenic, antimony, tellurium, tin, &c.; and in this class are also included sulphuretted hydrogen, bisulphide of carbon, and selenium and sulphocyanogen: the sulphur bases include the protosulphides of the metals of the alkalies and alkaline earths.

Compounds formed by the union of sulphur acids with sulphur bases are the *sulphur salts.*

The close chemical analogy between sulphur and oxygen is further seen on considering the constitution and properties of the following compounds of the two elements.

CO_2	CS_2	KO, AsO_3	KS, AsS_3
KO	KS	KO, AsO_5	KS, AsS_5
KO, CO_2	KS, CS_2	FeO	FeS
AsO_3	AsS_3	Fe_2O_3	Fe_2S_3
AsO_5	AsS_5	F_3O_4 (magnetic)	Fe_3S_4 (magnetic)

SULPHUR (in medicine) is an elementary principle which occurs in great abundance in the mineral, sparingly in the vegetable, and still more sparingly in the animal kingdom. In the vicinity of volcanoes sulphurous fumes issue copiously from the ground, and many mineral waters owe their peculiar odours and much of their virtues to sulphurous impregnations. Plants which contain it have often an offensive smell, to which most probably it contributes, constituting the *allyl* oils, such as asafœtida, garlic, and mustard, in which last it occurs as a constituent of myronic acid, a portion of which probably attaches to the volatile oil of mustard, the odour of which is stronger and more offensive than that of garlic and asafœtida combined. In animals it occurs in conjunction with albumen, and hence white of egg blackens silver egg-spoons.

For medical purposes, it should be as pure as possible, but in the two forms in which it occurs it is seldom perfectly free from admixture. Sublimed sulphur (flowers of sulphur) generally contains some sulphurous acid, which renders it slightly pungent; and precipitated sulphur, or milk of sulphur, mostly contains sulphate of lime. Of the two forms, precipitated sulphur, owing to the extremely fine state of subdivision in which it exists, is in equal quantities more powerful than the sublimed when freed from the large portion of sulphate of lime.

Sulphur is insoluble in water, very sparingly in alcohol, but soluble in oils, both fixed, such as linseed, and volatile, such as turpentine; with the former of which it forms the *balsamum sulphuris simplex,* with the latter the *balsamum sulphuris terebinthinatum.*

Though devoid of any marked sensible qualities, sulphur acts as a stimulant to the living tissues. Applied to the sound skin, it seems to have no effect upon it, but placed in contact with an ulcerated surface, it irritates and excites an inflammatory action. Large doses, such as a pound, given to horses, prove fatal by producing violent inflammation, recognisable during life by the symptoms, and after death by the morbid appearances. These may not have been due entirely to the sulphur, but to the tersulphide of arsenic (orpiment) with which sulphur is often contaminated. Hence the increased redness and sensibility of parts affected with cutaneous eruptions when sulphur is applied to them. It is clear therefore that it is by exciting to new action the unhealthy structures that it effects a cure of these diseases, and not by causing a repulsion or transfer of it to some other quarter, though this not unfrequently follows the too rapid healing of such complaints, if they have been spread over a large surface. Taken internally, sulphur gives rise to two distinct orders of effect: the one, its action on the intestinal canal; the other, upon the system generally. Small doses, if they do not increase the digestive power, at least do not disturb it; but larger cause a disagreeable sensation in the epigastric region, followed by alvine dejections, which are generally gentle, and without colic or griping. When it causes alvine evacuations, it does not produce marked general effects; but when given in small doses, with a sufficient interval between each to favour its absorption, its general action is commonly very apparent. The pulse becomes more frequent, the animal heat and perspiration are increased, and the presence of sulphur may be recognised in all the excretions of the body, or a transudation of it in the form of hydrosulphuric acid (sulphuretted hydrogen). In this way silver worn in the pocket of a person using sulphur becomes blackened.

The long-continued use of it gives rise to still more obvious stimulant effects. General excitement of the system takes place, increased arterial action leads to hæmorrhages, &c., accompanied by restlessness, sleeplessness, and thirst. The appearance of these symptoms should point out the propriety of suspending its further use till they can be removed by antiphlogistic means.

Sulphur should not be used for very plethoric individuals, or those inclined to high vascular action, till those states have been lessened by diet and other means.

Internally sulphur has been given in chronic catarrhs and humid coughs, as well as in some of the forms of asthma. From the power which sulphur undoubtedly possesses over mucous membranes, especially the bronchial, it is often serviceable; but in the asthmatic affections complicated with organic disease of the heart or great vessels, nothing can be more hurtful.

In chronic rheumatism sulphur, from its diaphoretic properties, is of much utility either alone or with antimonials. In those forms of dysentery which may be regarded as rheumatism of the intestines, sulphur is perhaps the best aperient in combination with ipecacuanha. It is also beneficial in those forms of paralysis which have resulted from rheumatism. It is stated to effect a cure of intermittents, and considering its power of rousing the vascular system, and its subsequent diaphoretic action, it may be used in those cases where arsenic fails and quinine is too expensive.

Sulphur is given as a laxative in hæmorrhoids, stricture of the rectum, and habitual constipation. For these cases it is usually combined with bi-tartrate of potash, or magnesia, or electuary of senna. A small quantity of the compound cinnamon-powder, or aromatic confection, is a valuable addition, as it lessens any tendency to griping, and also restrains the disposition to the disengagement of sulphuretted hydrogen gas, which is often a distressing consequence of the use of sulphur. The dose varies much in different individuals, but in all cases it should be ample, as an inefficient quantity is most prone to generate flatus. Persons of a sedentary habit, afflicted with constipation, find this combination of unspeakable service, as, unlike many others, it is not followed by greater constipation than before, but keeps the bowels moderately open for a considerable time. It is one of the most appropriate medicines for children or pregnant females.

Sulphur is generally given internally at the same time that it is used externally for the cure of cutaneous diseases. For one of these (*scabies*) it is regarded as almost a specific. Sulphur ointment is the form generally employed for this disease. It should never be applied to more than a fourth part of the body at one time. The compound sulphur ointment is more powerful, but requires still more caution in its employment from the veretrine it contains. In workhouse practice, the preferable mode of employing sulphur is by uniting it with soft-soap, which not only does not stain and grease the clothes, but assists in cleansing them as well as the patients when washed. Besides, the potash of the soap aids the cure. Many cutaneous diseases are more readily cured by a combination of sulphur with potash than by either singly. This combination, called *Potassii sulphuretum,* or liver of sulphur, may be applied in various ways, particularly in baths, forming artificial Harrowgate-water. The natural waters of Harrowgate, Moffat, and other sulphurous springs, owe their peculiarities to it.

Sulphur in combination with iodine, forming iodide of sulphur, when made into an ointment with a large quantity of lard or cerate, is a valuable agent in some cutaneous diseases. Sulphur sprinkled over the leaves of the vine is almost a certain preventive of the *oidium Tuckeri* or vine scourge. It is useful also for hops. See 'Gardeners' Chronicle,' March 30, 1861, p. 293, nor is it powerless against the potato disease. See 'Gardeners' Chronicle,' March 16, 1861, p. 241.

Sulphur in a state of combustion evolves sulphurous acid gas. This is sometimes employed as a fumigation in some obstinate cutaneous affections, especially *psoriasis inveterata,* which often continues about the joints, especially the elbow, when it has been cured in every other part. The employment of this requires caution, and on no account must the face be exposed to it, as it is irrespirable.

SULPHUR TRADE. Sulphur exists in Sicily, Iceland, Teneriffe, St. Vincent's, and some other places; but the expense of obtaining it from most of those countries is so great, that Sicily is almost the only source of supply. From that country England and France take more than 90 per cent. of the whole quantity exported. The average consumption of England in the five years, from 1820 to 1824, was 7080 tons. In 1825 the duty was reduced from 15*l.* to 10*s.* a ton, and in the following ten years the annual consumption averaged 15,140 tons; in 1837 it amounted to 37,486 tons. The Sicilian sulphur-mines are the property of individuals, and several English firms settled in Sicily are engaged in the trade. In 1836 M. Taix, a Frenchman, laid before the Sicilian government a project for establishing a company which was to have the exclusive right during ten years of purchasing Sicilian sulphur at fixed prices, on condition of spending 10,000*l.* a year in constructing roads, and exporting one-third of the quantity produced in Sicilian vessels. The British merchants becoming alarmed, the Sicilian government, in reply to the British ambassador, stated that no such project would be adopted. It would have been in direct contravention to certain commercial treaties between the two governments. The Sicilian government did, however, enter into a contract with M. Taix; and on the 4th of July, 1838, notice was given at Palermo that the monopoly would come into operation on the 1st of August ensuing. The negotiations respecting this monopoly were conducted with great secresy, and it came into operation so suddenly that twenty-four vessels lost their cargoes. The British lessees of mines, and all others, were compelled to produce only a fixed quantity of sulphur; prices rose from 6*l.* 10*s.* or 7*l.* to 13*l.* and 14*l.* per ton, and contracts could not be completed. At length the British government took very decided steps to put an end to a monopoly established in the face of commercial treaties: the coasts of Sicily and Naples were blockaded by our ships of war; and the Sicilian government, no longer daring to uphold the monopoly, accepted the mediation of the king of the French in adjusting the dispute with the British government. The monopoly was abolished in July, 1840, and a mixed English and Sicilian commission was appointed in November to investigate the claims of British subjects whose interests had been injured by it. The claims amounted to 65,610*l.*, of which 21,307*l.* was awarded; and as it was stipulated that the awards should bear interest at the rate of 6 per cent. so long as they remained unsettled, the Sicilian government agreed, in January, 1842, to pay them without any delay. The sulphur trade was thereupon placed on the same footing as before the date of the contract with M. Taix.

A correspondent of the *Times* newspaper, while noting and recording the exploits of Garibaldi in Sicily in 1860, turned aside to visit the principal sulphur district, and to give an account of the present mode of conducting the trade. The chief mines are at Villarosa, Santa Catalda, and Terra di Falco. The sulphur lies imbedded in tufa, gypsum, or limestone, mostly at the sides of mountains. Sometimes the vein is so thick as to require pillars of sulphur to be left to support the roof of the mine. The smelting, or preparation for market, used to be conducted in the open air; but as this injured the quality, and moreover tainted the air of the neighbourhood, another plan is now adopted. A round space is cleared on the side of a mountain, about sixty feet in diameter, with a high wall to bound it on the outer or lower side. An orifice in this side is formed, temporarily plastered over. The sulphur-stone is placed in regular layers on the open space, heaped up conically very high, and is well covered with the rubbish resulting from former smeltings. Fire is applied through a small opening, which is then closed up; and the stone burns for about three weeks, as much excluded from the air as possible. When the whole of the sulphur in the stone has become liquefied, the hole is tapped, and a black pitchy liquid runs out into troughs; this liquid cools to a yellow solid, clean or dirty according to its quality. The price of the sulphur thus obtained is greatly increased by the difficulty of transport. There is no road from the mines suitable for vehicles. Mules carry the sulphur to the nearest town, whence it is conveyed in two-horse carts to Girgenti.

SULPHURATION, or SULPHURING, is the process of bleaching employed to give whiteness to silk and woollens by exposing them to the fumes of burning sulphur. For this process a detached chamber, without a chimney, is made use of; but so constructed that, when required, a current of air may be passed through it. In sulphuring silk, about 100 pounds, stretched on perches, are placed at a height of nearly seven feet; and about two pounds of sulphur, reduced to coarse powder, are put into an iron pot containing a small quantity of ashes; the sulphur is fired in several places, and the chamber well closed to prevent the loss of sulphurous fumes; afterwards the windows are opened to let them escape and to dry the silk. In winter, after the smell of the sulphurous vapour has ceased, the windows are shut, and charcoal is burnt in the chamber, in order that the silk may be dried. By this operation the silk becomes perfectly white, and is rendered fit for subsequent operations. Woollen cloths are treated nearly in the same manner. Straw hats and bonnets are also sulphured.

SULPHURETTED HYDROGEN. [Sulphur.]

SULPHURIC ACID. [Sulphur.]

SULPHURIC ACID, *Medical Properties of.* This, which is regarded as the most potent of the mineral acids, is never taken internally in a concentrated state except by accident, or with the intention to commit suicide or murder. In such cases it acts as a violent corrosive poison, causing complete disorganisation of the tissues it comes in contact with, its course being obvious from the black and charred state of the parts. This effect it is thought to produce from its strong affinity to water, depriving the tissues of its elements, and leaving the carbon free. This peculiarity distinguishes poisoning by it from the other mineral acids. Notwithstanding the extensive destruction of important organs, such as the stomach, immediate death rarely results from it, but the patient lingers sometimes for days, and in some cases ultimately recovers.

Sulphuric acid is sometimes employed in an undiluted state as a caustic application to the bites of rabid animals, or to destroy warts or portions of the eyelids in entropium and ectropium.

In a considerably diluted state, if it be applied to the skin, it occasions a painful impression, followed by numbness and a contraction of the parts, and even whiteness, owing to the diminished calibre of the capillaries. But shortly the afflux of blood to the part recurs, and soon increases, so that the action of the vascular system appears to become more developed than before. As it is presumable that a similar series of actions takes place when received in a diluted form into the stomach, by bearing these phenomena in mind it is possible to explain its therapeutic influence in many of the cases where it is used.

Taken internally in a diluted but still strong state, it makes a powerful impression on the stomach, followed by an instantaneous sympathetic chill of the whole system: hence its power in checking hæmorrhage long before its particles can be received into the circulation and constringe the vessels by immediate contact with their sides. From the same cause it acts as a useful refrigerant in fevers and other inflammatory diseases when the animal temperature is too high. In many of the transient diseases of the skin attended with much heat and itching, a solution of sulphate of magnesia, with an addition of dilute sulphuric acid, quickly relieves them. It has also been given at a late stage of typhus in some mild diluent, such as barley-water. In combination with cinchona, it is of decided utility in *purpura hæmorrhagica.* Nothing save oxide of zinc so certainly checks the colliquative sweats which attend hectic fever as the compound infusion of roses. In chronic diarrhœa and dysentery it is also sometimes of service. Hæmorrhoidal fluxes are often restrained by its use. In some forms of dyspepsia it is a valuable tonic, and may be longer persevered with than any other mineral acid except phosphoric. In calculous diseases with a phosphatic diathesis, it is much to be commended, from the length of time it can be used. In such cases it is best given in infusion of camomile made with cold water. It is employed largely diluted as a gargle in the sore-throat of scarlet fever. Many cases of cutaneous diseases have been cured by the internal use of sulphuric acid. The aromatic sulphuric acid, called elixir of vitriol, has more tonic properties than the simple acid. A few drops of it, ten or twelve, in a cup of cold water, relieve very certainly the squeamishness of the stomach which is felt in the morning after an excess of wine. In case of poisoning by sulphuric acid, lime-water, calcined magnesia, or plaster from the wall, or a solution of soap, should instantly be given.

The *unguentum acidi sulphurici* is a most effectual application in obstinate cases of itch. It chars the linen.

SULPHURIC ETHER. [Ethyl.]

SULPHUROUS ACID. [Sulphur.]

SULTA'N, an Arabic word meaning "a despotic ruler, or a man who is the arbiter of the life and property of a set of men." It is the usual title of royalty among the Arabs and Turks. From sultán the Italians have made their *soldano*, and the Spaniards have their *sultán.* The lawful wife of a sultán, who has children by him, is called by us a sultana.

SUM (in the sense of integral). Before the organisation of the formal integral calculus, the isolated operations of integration which were attained were expressed in words borrowed apparently from the notion of indivisibles. [Cavalieri, in Biog. Div.] Thus the title of one of Halley's papers is 'An Easy Demonstration of the Analogy of the Logarithmic Tangents to the Meridian Line or Sum of the Secants.' Here the sum of the secants means what we should now denote by $\int \sec x.dx.$

SUM AND DIFFERENCE. There is no need to define the arithmetical meaning of these terms: a few words only are necessary to put them in their proper position in algebra. When quantities receive their proper algebraical signs, and those signs their interpretations [Algebra; Sign; &c.], they are said to be added to a quantity when they are allowed to produce their effect, and subtracted when they are allowed to produce a contrary effect. And when quantities are put together so that each produces its simple effect, they are said to be added together; while any parcel which is either withdrawn, or compensated by others of equal and opposite effects, is said to be subtracted. We are not here discussing principles, but settling terms; and it is enough if the notions appended to them be proper foundations for clear and good deduction; and an additional advantage if common ideas and received phraseology be also suited, provided that nothing be assumed from such ideas and phraseology to the prejudice of the dependence of the deduction upon the prescribed definitions.

To form a just idea of the property of any person, we take the sums which he owes away from his assets; that is, we take away, not his debts, but sums out of his assets equal to his debts. To say that this is taking away his debts would not be correct; for taking away his debts would be merely destroying his liabilities, without making his assets answerable: a person who himself pays another's debts takes them away. A court of justice which decides a claim against the assets of any one, annexes or puts on a liability; and this is in algebra *adding:* if the decision should be reversed on appeal, this liability to pay is removed, and this is in algebra subtracting. In the phrase "to gain a loss," the word "gain" is used in the preceding sense of simple adjunction: if it were as common to talk of losing a loss, the verb to lose would be used in the sense of to remove or to get rid of: the other form of the word would be less of a bull, for to *loose* a loss would be to detach it. In a third form, the idiom is still plainer; to *release* [from] a loss would be precisely the idea of algebra, answering to subtracting a loss.

SUM, SUMMATION. In the articles Integration, Finite, and Progression, some ideas and rules are given upon the subject of the summation of a finite number of terms of a series; and in Series will be found examples of the inverse process of development. In the present article we are to give some account of the methods of actual summation which are in use in the higher branches of mathematics; referring for the demonstrations to the Differential Calculus in the 'Library of Useful Knowledge' (cited by the letters D. C.). We shall dwell upon this at greater length than would appear to be altogether in keeping with the extent of the articles above cited; the reason being that many persons to whom the following rules may be practically useful never hear of them because they are locked up in Treatises on the Differential Calculus, or in works which are not generally read. The merest elements of differentiation and integration are enough to enable a beginner to use results the *proof* of which must be reserved for a more advanced stage of his progress.

1. When the terms of a series are alternately positive and negative, as in $a_0 - a_1 + a_2 -$ &c., the sum of the series *ad infinitum* may thus be expressed [DIFFERENCE] (D. C., pp. 556–560) :—

$$\frac{a_0}{2} - \frac{\Delta a_0}{4} + \frac{\Delta^2 a_0}{8} - \frac{\Delta^3 a_0}{16} + \ldots\ldots$$

which is frequently more convergent than the series itself; in fact, the less convergent the series is, the more convergent is the transformation. Dr Hutton's method of obtaining the transformed series is as follows: —Take a number of the successive sums a_0, $a_0 - a_1$, &c., and let

$$\text{s}_0 = 0\,,\ \text{s}_1 = a_0\,,\ \text{s}_2 = a_0 - a_1\,,\ \text{s}_3 = a_0 - a_1 + a_2\,,\ \&\text{c.}$$

Take the half sum of s_0 and s_1, the half sum of s_1 and s_2, the half sum of s_2 and s_3, &c. Let these be T_0, T_1, T_2, &c. Repeat the process: take the mean of T_0 and T_1, that of T_1 and T_2, &c., which call U_0, U_1, &c. Take the mean of U_0 and U_1, that of U_1 and U_2, &c., which call V_0, V_1, &c. Then the set S_0, T_0, U_0, V_0, &c., will severally approach nearer and nearer to the series required; in fact

$$\text{T}_0 = \frac{a_0}{2},\ \text{U}_0 = \frac{a_0}{2} - \frac{\Delta a_0}{4},\ \text{V}_0 = \frac{a_0}{2} - \frac{\Delta a_0}{4} + \frac{\Delta^2 a_0}{8},\ \&\text{c.}$$

It would however be somewhat easier to proceed as follows:—having formed differences as far as may be thought necessary, say up to $\Delta^n a_0$, take half $\Delta^n a_0$ from $\Delta^{n-1} a_0$, half the result from $\Delta^{n-2} a_0$, half the result from $\Delta^{n-3} a_0$ and so on until a_0 has been used: after which halve the result again. In either case we need not begin at the beginning of the series: if it be more convenient to begin after a_{10} let $\text{A}_{10} = a_0 - a_1 + \ldots\ldots - a_9 + a_{10}$, and calculate this separately: then calculate $a_{11} - a_{12} + \ldots\ldots$ from the rule, and we have $\text{A}_{10} - (a_{11} - a_{12} + \ldots)$ for the series required. The following is an instance from Dr. Hutton ('Tracts,' vol. i., p. 191), the series being $1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \ldots\ldots$

Sums.	The several orders of means.					
1						
0·5						
833333						
583333						
783333						
616666	688095					
759524	607024	692560	693056			
634524	690080	693552	693205	693131	693144	
745635	695635	692858	693110	693158	693150	693147
645635	691090	693362	693173	693142		
736544	694878	692984				
653211						

The result is ·693147, which is correct to the sixth place, and is more than could be got from the series itself by actual summation of a million of its terms. Dr. Hutton begins in forming the means with $1 - \frac{1}{2} + \ldots\ldots + \frac{1}{6}$: we shall therefore try the other method, beginning with $\frac{1}{7}$.

$1 - \frac{1}{2} + \ldots - \frac{1}{6} =$ ·6166666
·0764795

·6931461

This last process will be found on trial the easier of the two.

2. The sum of the series $a_0 - a_1 + a_2 -$ &c. *ad infinitum* may be thus expressed (D. C., p. 555) :—

$$\frac{a_0}{2} - \frac{a_0'}{4} + \frac{a_0'''}{48} - \frac{a_0^{\text{v}}}{480} + \frac{17a_0^{\text{vii}}}{80640} - \&\text{c.}$$

where a_x, a function of x, generates the several terms by making $x = 0, 1, 2$, &c., in succession, and a_0', a_0''' a_0^{v}, &c., mean the values of the odd differential co-efficients of a_x when x is $= 0$. This transformation is useful when the values just mentioned are not considerable. Another form, which is sometimes more convenient, is—

$$\frac{a_0}{2} - \frac{a_0'}{4} + \frac{a_0'''}{2\,[4]} - \frac{3a_0^{\text{v}}}{2\,[6]} + \frac{17a_0^{\text{vii}}}{2\,[8]} - \&\text{c.}$$

where $[m]$ means $1\,.\,2\,.\,3 \ldots\ldots m$. In the instance before us, and that we may begin from the same term as before, let

$$a_x = \frac{1}{7+x},\ a_0 = \frac{1}{7},\ a_1 = \frac{1}{8},\ \&\text{c.}$$

$$a_0 = -\frac{1}{7^2},\ a_0''' = -\frac{[3]}{7^4},\ a_0^{\text{v}} = -\frac{[5]}{7^6},\ a_0^{\text{vii}} = -\frac{[7]}{7^8};$$

whence the series required from and after $\frac{1}{7}$ is—

$$\frac{1}{14} + \frac{1}{4\,.\,7^2} - \frac{1}{2\,.\,4\,.\,7^4} + \frac{3}{2\,.\,6\,.\,7^6} - \frac{17}{2\,.\,8\,.\,7^8}.$$

Call these terms (1), (2), &c., and begin with $\frac{1}{2} + \ldots - \frac{1}{6}$, or ·616666 ....: we have then—

	·6166666667
(1)	·0714285714
	·6880952381
(2)	·0051020408
	·6931972789
(3) −	·0000520616
	·6931452173
(4)	·0000021250
	·6931473423
(5) −	·0000001843
	·6931471580
True Answer	·6931471806

The result of this comparatively easy process is as correct as the summation of fifty millions of terms of the series.

3. The sum of any large number of terms of a series may be found by summing the whole series *ad infinitum*, then doing the same with the terms following the last term which is to be retained, and subtracting the second result from the first.

4. The sums of such series as are included under $1^{-n} + 2^{-n} + 3^{-n} +$ &c., such as

$$1 + \frac{1}{4} + \frac{1}{9} + \ldots,\ 1 + \frac{1}{8} + \frac{1}{27} + \&\text{c.}$$

continued *ad infinitum*, may be given for reference in the following table. The first term will presently be explained. More will be found in D. C., p. 554.

n.	Sum of Series.
1	·5772156649015329 + log ∞
2	1·6449340668482264
3	1·2020569031595943
4	1·0823232337111382
5	1·0369277551433700
6	1·0173430619844491
7	1·0083492773819227
8	1·0040773561979443
9	1·0020083928260822
10	1·0009945751278180
11	1·0004941886041194
12	1·0002460865533080

The first line means that the sum of the series is infinite, but that the expression for a large number of terms contains the logarithm of that number, which being removed, the rest of the expression approximates as the number of terms increases, to ·577215 ....

5. The series $1^{-n} - 2^{-n} + \ldots$ is connected with $1^n + 2^n + \ldots$ by the following simple law:—

$$1^{-n} - 2^{-n} + 3^{-n} - \ldots = \left(1 - \frac{1}{2^{n-1}}\right)(1^{-n} + 2^{-n} + 3^{-n} + \ldots)$$

6. The sum $a_0 + a_1 + a_2 + \ldots$ *ad infinitum* may be thus transformed:—

$$\int_0^\infty a_x dx + \frac{1}{2}\,a_0 - \frac{1}{6}\,\frac{a_0'}{2} + \frac{1}{30}\,\frac{a_0'''}{[4]} - \frac{1}{42}\,\frac{a_0^{\text{v}}}{[6]} + \&\text{c.}$$

where the notation is as previously explained, and $\frac{1}{6}$, $\frac{1}{30}$, &c., are the series of NUMBERS OF BERNOULLI. To apply this, for example, to

$1^{-2}+2^{-2}+3^{-2}+\ldots$, it will be convenient to begin from some term which will make the series more convergent. Let $a_x=(10+x)^{-2}$: we have then for $10^{-2}+11^{-2}+\ldots$ the following:—

$$\frac{1}{10}+\frac{1}{2}\,\frac{1}{10^2}+\frac{1}{6}\,\frac{1}{10^3}-\frac{1}{30}\,\frac{1}{10^5}+\frac{1}{42}\,\frac{1}{10^7}-\&c.,$$

which may be easily calculated, and the preliminary series $1^{-1}+\ldots+9^{-2}$ may then be added.

7. The finite series $a_0+a_1+a_2+\ldots+a_{x-1}$ (x terms) is thus transformed (D. C., p. 266):—

$$\int_0^x a_x\,dx-\frac{1}{2}(a_x-a_0)+\frac{1}{6}\,\frac{a_x'-a_0'}{2}$$
$$-\frac{1}{30}\,\frac{a_x'''-a_0'''}{[4]}+\frac{1}{42}\,\frac{a_x^{\mathrm{v}}-a_0^{\mathrm{v}}}{[6]}-\frac{1}{30}\,\frac{a_x^{\mathrm{vii}}-a_0^{\mathrm{vii}}}{[8]}+\&c.,$$

in which the detached coefficients are again the numbers of Bernoulli. Or, if the sum of the series *ad infinitum* be known, s, the preceding may be expressed as follows:—

$$s-\int_x^\infty a_x\,dx-\frac{1}{2}\,a_x+\frac{1}{6}\,\frac{a_x'}{2}-\frac{1}{30}\,\frac{a_x'''}{[4]}+\&c.$$

But when the complete series is divergent, the set of terms $a_0+a_1+\ldots+a_{x-1}$ may be thus expressed:—

$$c+\int_0^x a_x\,dx-\frac{1}{2}\,a_x+\frac{1}{6}\,\frac{a_x'}{2}-\frac{1}{30}\,\frac{a_x'''}{[4]}+\&c.,$$

where c must be determined by an instance. Thus if we make $a_x=(1+x)^{-1}$ we have for $1+2^{-1}+\ldots+x^{-1}$ the following series:—

$$c+\log^{*}(1+x)-\frac{1}{2}\,\frac{1}{1+x}-\frac{1}{12}\,\frac{1}{(1+x)^2}+\frac{1}{120}\,\frac{1}{(1+x)^4}-\&c.$$

Add $(x+1)^{-1}$ to both sides, and write $x-1$ for x, which gives for $1^{-1}+\ldots+x^{-1}=$

$$c+\log x+\frac{1}{2x}-\frac{1}{12x^2}+\frac{1}{120x^4}-\&c.$$

To determine c, choose such a number for x as shall make this series convergent, say $x=10$. Calculate $1^{-1}+\ldots+10^{-1}$, term by term, which is easily done, and equate the sum to

$$c+2{\cdot}302585093+\frac{1}{20}-\frac{1}{1200}+\frac{1}{1200000}-\&c.,$$

which gives $c={\cdot}5772156\ldots$, the number mentioned at the head of the table for series of inverse powers already given. With the value of c thus determined, and a sufficient table of logarithms, the larger the number of terms in $1^{-1}+\ldots+x^{-1}$, the more easily is its approximate value calculated.

8. The series $\log 1+\log 2+\ldots+\log x$ is of sufficient importance to have an article to itself. Make $a_x=\log(1+x)$, and proceed as in the last example, which will give for $\log(1.2.3\ldots x)$ the following series:—

$$c+\log x.x-x+\frac{1}{2}\log x+\frac{1}{12x}-\frac{1}{360x^3}+\ldots$$

c might be determined as before, but a particular mode of investigation shows it to be $\log(\sqrt{2\pi})$, where $\pi=3{\cdot}14159\ldots$, as usual. This gives

$$1.2.3\ldots x=\sqrt{2\pi x}\;x^x.\;\epsilon^{-x+\frac{1}{12x}-\frac{1}{360x^3}+\&c.}$$

a result of the greatest use, particularly in the more complicated applications of the theory of probabilities.

9. The series $0^n+1^n+2^n+\ldots+x^n$, in which $a_x=x^n$, n being integer and positive, is by the case of § 7, and adding x^n to both sides,

$$c+\frac{x^{n+1}}{n+1}+\frac{x^n}{2}+\frac{1}{6}\,\frac{nx^{n-1}}{2}-\frac{1}{30}\,\frac{n(n-1)(n-2)x^{n-3}}{2.3.4}+\&c.;$$

but this vanishes when $x=0$, whence c must be taken accordingly in every instance. To take an example which shall require a little extension of the series beyond the terms used above, let it be required to find $0^7+1^7+\ldots+x^7$. Looking at the article NUMBERS OF BERNOULLI, we find a supply of coefficients in

$$\frac{1}{6}\quad\frac{1}{30}\quad\frac{1}{42}\quad\frac{1}{30}\quad\frac{5}{66}\quad\frac{691}{2730},$$

and the sum required is

$$c+\frac{x^8}{8}+\frac{x^7}{2}+\frac{1}{6}\,\frac{7x^6}{2}-\frac{1}{30}\,\frac{7.6.5x^4}{2.3.4}+\frac{1}{42}\,\frac{7.6.5.4.3x^2}{2.3.4.5.6}$$
$$-\frac{1}{30}\,\frac{7.6.5.4.3.2.1}{2.3.4.5.6.7.8},$$

which vanishes when $x=0$, whence

$$c+\frac{1}{30}\,\frac{7.6.5.4.3.2.1}{2.3.4.5.6.7.8}=0,$$

and the rest may be reduced to

$$\frac{x^8}{8}+\frac{x^7}{2}+\frac{7x^6}{12}-\frac{7x^4}{24}+\frac{x^2}{12},$$
$$\text{or}\qquad(3x^8+12x^7+14x^6-7x^4+2x^2)\div 24.$$

SUMACH, or SWAMP SUMACH (*Rhus Toxicodendron*), a North American shrub, possessing peculiar properties, from which it has been named also the Trailing Poison Oak. The leaves, which are trifoliate, thin, shining when fresh, of a dark-green colour, are the only parts officinal in this country. But the leaves, branches, and flowers contain a milky juice which blackens on exposure to the air, and may be used as an indelible ink when applied to cotton or linen. Besides this very acrid milk, the plant, when not exposed to the sun's rays, by growing in the shade, or during the night, exhales a hydrocarburetted gas, which acts very potently on persons of a peculiar susceptibility, when exposed to it. In two or three days after touching or being very near the plant, the skin inflames and swells, being attended with intense burning pain. If the face be affected, the eye-lids are so tumefied as to close up the eyes; and the whole head is swelled and covered with little blisters containing serum. Occasionally the whole body is enormously swollen and covered with similar vesicles. When the inflammation and swelling have subsided, the skin desquamates, and an intolerable itching is felt for several days afterwards. These symptoms closely resemble erysipelas, and are moderated by treatment suited to that complaint. Professor Barlow states that the best application is a weak aqueous solution of bichloride of mercury. All persons however should avoid touching any sumach which has milky juice.

The leaves, or an extract of the inspissated juice of this plant, have been recommended in several diseases, particularly herpes, paralysis, and consumption. It is little used in this country, but it appears entitled to some confidence in local paralysis, such as that of the jaw. It must be given with caution, as large doses act like narcotico-acrid poisons.

SUMBUL, written also Sunbul, is a generic term applied to many fragrant roots, one or more of which have been already noticed under SPIKENARD. What is now to be noticed is a root recently introduced into medical practice, of which there are two, perhaps three varieties, the source of none of which is accurately known, though conjectured to be the produce of some umbelliferous plant, to which the name of *Angelica moschata* has been given. One is designated Russian sumbul, another, Indian sumbul; while a third is called Cathayan sumbul, which perhaps scarcely differs from the first kind, which is said to reach Moscow through Kiachta, the same channel as the Russian rhubarb. The Russian is the most powerful in odour, which is more or less musky. The taste is bitter and slightly acrid. The analysis shows it to contain a volatile oil, two balsamic resins, one soluble in ether, the other in alcohol, with wax, starch, &c., and a peculiar acid termed sumbulic. It yields its properties to alcohol or ether; it is also given in powder, watery infusion, decoction, or extract. The balsamic resins and oil impart a stimulating power to it, which renders it useful as an antispasmodic, and it is especially available in hysterical affections; and like other medicines of the same class, it would appear to be sedative, as it calms nervous restlessness and procures sleep. It has also been recommended in dropsy and atrophy.

SUMBULIC ACID. [ANGELIC ACID.]

SUMMARY JURISDICTION. [JUSTICES OF THE PEACE.]

SUMMER. [WINTER, &c.]

SUN (Latin, *sol*; Greek, ἥλιος, Hēlios). In the present article we confine ourselves to the astronomical characters of the sun's orbit, and to what we know of its physical constitution. For more particulars on the measurement of time, see TIME; on chronology as dependent on this body, and on the more common characters of its motion, see YEAR. See also MOON; SEASONS; ASTRONOMY; ZODIAC (on mythology); ZODIACAL LIGHT; TWILIGHT; &c.

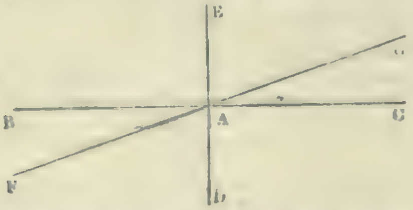
It is needless to say that if the utility of the subject of an article were to determine its length, the one we are now commencing ought in justice to occupy several volumes of the work: were we, however, seriously to mete out the importance of the sun in columns of a Cyclopædia, our panegyric would not be more quaint than that of Sir John Hill, who says that this luminary is "enough to stamp a value on the science to which the study of it belongs." In relation to astronomy this is particularly true; for it would be possible to preserve life on the earth, and to keep order, without any knowledge of the moon, planets, or stars; but to do this without any acquaintance with the sun's motions would be absolutely impossible. The source of light and heat, and through them of the alternations of the vegetable world, is, in the highest secondary sense, the giver and sustainer of life; but this very importance ensures names to so many results of solar phenomena, that the present article is stripped of details, by their entering more appropriately into others.

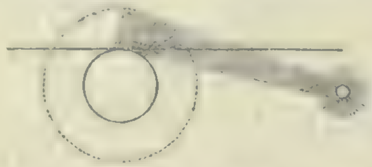
---

[*] The Naperian logarithm, which is always used in mathematical investigations, unless the contrary be expressed. It is 2·302585093 × comm. log.

The motions of the sun are in fact those of the earth, written in the heavens. If the diurnal motion of the earth were stopped, the sun would appear to move slowly among the stars, from west to east, at the rate of about twice its own diameter in twenty-four hours by the clock. This [Motion] is the consequence of the orbital motion of the earth, which is communicated in appearance to the sun. If the earth's orbital motion were stopped, the diurnal motion continuing as usual, the sun would appear to move round daily, from east to west, as at present; but since there would then be no motion of that body among the stars, those stars which are at any one time hidden by the daylight would always be hidden, and the face of the heavens at any given hour of night would be the same at all times of the year. The effect of the orbital motion of the earth combined with the diurnal motion is that the solar day, or the interval between two meridian passages of the sun, is a little longer than the sidereal day (about four minutes), or than the actual revolution of the earth; so that all the stars have their turn, and every star in the course of the year comes on the meridian at every period of the natural or solar day. [Synodic; Time.]

The great phenomena of day and night are attended with very different circumstances in different parts of the globe. We are not speaking now of the high polar regions, north and south, in which the sun never sets for days together, but of those parts of the earth in which there is actual appearance and disappearance of the luminary, or real day and night. Let us take the day of the vernal equinox as a specimen, when the sun is in the equator (we presume in our reader a knowledge of the terms and notions in Sphere, Doctrine of the). If we take one fixed line to represent the horizon of different places, as B A C, the sun will rise to a place on the equator so as to move along the circle D A E, and to come directly up from the horizon; while at a place near the pole it will move, relatively to the horizon (still B A C), along the circle F A G. Now the first evidence which the sun gives of its approach is this (the diagram, though of very distorted dimensions, may be of use): before it has risen above the horizon of a place, so as to be visible, it can throw its rays into the atmosphere above the place, which atmosphere reflects something both of light and heat to the place itself. This period is called the twilight, and it is said that there is more or less of twilight as long as the sun is not more than 15° below the horizon; though certainly the twilight which saves candle-light does not last so long. But be the number of degrees which are allowed to twilight more or less, it is obvious that at the equator, where the whole of the sun's way is made directly to or from the horizon, the intermediate period of twilight must be much shorter than at a place near the pole, where the motion towards the horizon is very oblique, instead of being all ascent, as before rising, or descent, as after setting. The consequence is well known: in the tropics, the warning is short, and soon after the light begins to break the sun makes its appearance, and it is broad and hot day; while after the setting the light as soon disappears, and it is dark night. With us, on the contrary, and still more in higher northern latitudes, there is a long warning of the approach of the luminary before the sunrise, and a long remembrance of it after sunset. In all climates the transition from day to night is broken by the two circumstances mentioned in Seasons. In the same article it is pointed out that the heat received during the winter and summer halves of the year is the same over the whole earth.





Immediately after sunrise, the form of the luminary appears somewhat elliptic, the horizontal diameter being longer than the vertical one. This is the effect of Refraction, which varies so rapidly near the horizon that the upper end of the vertical diameter is less elevated than the lower end by a sensible quantity, while the two ends of the horizontal diameter are equally elevated. The same phenomenon occurs with the moon, when rising at the full, and would also be seen in the planets, if they were large enough in appearance. It must also be noted that both sun and moon appear larger when near the horizon; but this, as to the sun, is delusion, since when measured with instruments its apparent diameter is the same at all parts of the day. It is true that both bodies, when in the zenith, are nearer to the spectator than when in the horizon, by what may be called without error a semidiameter of the earth; the moon is near enough to show the effect of this in instrumental measurements of its diameter, but it is not so with the sun.

Before looking at what we know of the physical appearances of the sun, its distance from the earth must be mentioned, to which we may add at once the other elements of its orbit. Its equatorial horizontal Parallax, at its mean distance, is 8″·5776, and its apparent semidiameter 16′ 0″·9. It is then distant from the earth by 24,000 semidiameters of the earth, or about 95,000,000 miles. Its diameter is 111½ times as great as that of the earth, or upwards of 880,000 miles; and its bulk is 1,300,000 times as great as that of the earth. But its mass, as determined from its action on the planets, is only 355,000 times as great as that of the earth; whence its average density is only one-quarter of that of the earth. But this last result takes into the body of the sun all that is seen of it: if the surmise presently to be mentioned, of its having a luminiferous atmosphere of considerable extent, be well founded, the real body of the sun may have as much density as the earth, or more. It revolves on its axis in 25½ of our mean solar days; according to Delambre, in 25·01154 days: the axis being inclined to the ecliptic at an angle of 82½°.

The ecliptic is the circle in which the sun appears to move, in common language. In strictness, however, the earth does not move round the sun in a true plane, though it does so very nearly. The centre of gravity of the earth and moon (a point near the earth) does much more nearly describe a plane; that is, a spectator situated at that point would more nearly see the sun move in a great circle than we do. But to us, the sun is sometimes on one side and sometimes on the other of this mean ecliptic, and therefore generally has some *latitude*, though a very small one: the column entitled "the Sun's latitude" in 'The Nautical Almanac' is a puzzle to those readers whose astronomy is drawn from the usual elementary writings: in truth, it is only a fraction of a second, and the sun crosses the mean ecliptic twice in every lunation. The obliquity of the mean ecliptic, for January 1, 1860, is 23° 27′ 27″·38, and it is diminishing yearly by 0″·457: thus this same obliquity for January 1, 1842, is 23° 27′ 35″·60. If this diminution could go sufficiently far, it would in time bring the ecliptic and equator to coincidence, or equalise days and nights all over the world; and if it could be held to have continued long enough, would entitle us to presume that the poles were once in the plane of the ecliptic, or that every part of the earth went through all gradations in a year from equal days and nights to a polar day and a polar night. But the cause of this diminution of the ecliptic is known from the theory of gravitation; and it is also known that, under existing causes, it cannot be permanent, but must diminish in quantity and finally turn into an increase before its effect has amounted to many degrees. Persons acquainted with the phenomena of the heavens, but not with the results of the theory of gravitation, remembering the fact of tropical productions being found buried in high latitudes, sometimes imagine that they can look back to the time when the poles were so near the ecliptic, that these same high latitudes were within the tropics. This, however, is a pure fancy, and they had better imagine another cause; the one they think of will not do.

The mean longitude of the sun, at Greenwich mean noon on the 1st of January of the year $1800+t$, may be determined from

$$280^\circ\ 53'\ 32''\cdot75 + 27''\cdot605844t + \cdot0001221805t^2 - 14'\ 47''\cdot083f,$$

where f is the remainder of t divided by 4, or 4 if the remainder be 0; that is, the number of years after the *Julian* leap-year, or after the *Gregorian* leap-year for all years after 1804. The mean motion in longitude in a mean solar day is 59′ 8″·33.

The excentricity of the sun's orbit is ·016783568 (according to Laplace, ·01685318), or the greatest and least distances of the sun from the earth are in the proportion of 1·017 to ·983, or as 30 to 29, or more nearly as 91 to 88. The greatest equation of the centre [Time] is 1° 55′ 27″·3. The excentricity diminishes by ·00004163 in a century.

The mean longitude of the perigee, at noon, January 1, 1801, was 279° 30′ 5″·0. It has a real yearly increase of 11″·8, which, with the precession of the equinoxes, makes an increase of longitude of 61″·9.

The appearance of the sun is simply that of a ball of intense light, such as the human eye cannot bear, unless a hazy atmosphere or a dark glass be used as a screen. This light is so strong, that the brightest flames which human art can produce, when held before the sun, disappear, and ignited solids become dark spots. "The ball of ignited quicklime," says Sir J. Herschel, "in Lieut. Drummond's oxy-hydrogen lamp, gives the nearest imitation of the solar splendour which has yet been produced. The appearance of this against the sun was however, as described," merely a dark spot, "in an imperfect trial at which I was present. The experiment ought to be repeated under favourable circumstances." A very small portion of the rays collected into one spot [Burning-Glasses] is sufficient to melt metals. On examining the face of the sun with a telescope (of course with a dark glass before the eye), two circumstances are observed. The disc is not uniformly bright. "The ground is finely mottled," to use the words of the observer just quoted, "with an appearance of minute dark dots, or *pores*, which, when attentively watched, are found to be in a constant state of change. There is nothing which represents so faithfully this appearance as the slow subsidence of some flocculent chemical precipitates in a transparent fluid, when viewed perpendicularly from above; so faithfully, indeed, that it is hardly possible not to be impressed with the idea of a luminous medium intermixed, but not confounded, with a transparent and unluminous atmosphere, either floating, as clouds in our air, or pervading it in vast sheets and columns like flame, or the streamers of our northern lights." The mind is lost in wonder at the idea of such a body of luminous material; but it is important to remember that living, as we must, under an atmosphere, we cannot positively assert anything as to what may take place beyond it. It is possible, though not very probable, that we should neither feel sensible of light nor heat, if we could meet the sun's rays before they have entered the air.

The other circumstance which is noticed on the sun's disc is the existence of black spots, by the regular motion of which the rotation of the body on its axis has been determined. These spots are of various irregular shapes, and are always surrounded by a border or penumbra, not so dark as the spot. They are of various sizes, from the least visible to the twentieth part of the sun in diameter. In their neighbourhood are frequently observed streaks on the disc more luminous than the rest, called *faculæ*, in which streaks spots frequently begin their appearance. The spots themselves alter in size, and gradually vanish, lasting various times, from a few days to six or seven weeks; the borders approaching each other in a manner which calculation shows must answer to hundreds of miles a day. Various theories have been invented to account for them, but none which has any appearance of probability except that of W. Herschel ('Phil. Trans.,' 1801). He supposes that the sun has an atmosphere of greater density and depth than that of the earth; and that above this atmosphere, or else mixed with the higher strata of it, is another atmosphere of self-luminous clouds, of very variable depth, sometimes showing the lower atmosphere uncovered, which last reflects the light of the luminous atmosphere above it. A spot on the sun is a portion of the body of the sun itself, laid bare by some commotion which removes both atmospheres, or the greater portion of them: the penumbra round the spot, its never-failing attendant, arises from the ridges of the lower atmosphere, which form the banks of the opening. The faculæ, and general mottled appearance of the sun, arise from the luminous atmosphere having waves or ridges. From some measures of the light of different parts of the sun, Herschel thought that the non-luminous atmosphere reflects a little less than one-half the light it receives from the luminous atmosphere, and the solid body of the sun less than one tenth. He also supposed that the presence of spots and other disturbances indicated a large formation of heat and light in the sun, and was a prognostic of hot weather and fine seasons. This he imagined he had verified by such comparisons as existed of the state of the sun at different times with the prices of wheat immediately following: he found that, as far as his data went (and he gives a proper warning as to their insufficiency), the price of wheat always rose when the sun was without spots, and fell when they began to reappear. We have not heard of any extensive attempt to verify or refute this theory; but so far as the hypothesis of the two atmospheres is concerned, it is one of high probability: we could hardly ask for a likely result of such a combination which does not actually make its appearance. If it be correct, the sun may very possibly be a globe habitable by living beings, perpetually illuminated by its upper atmosphere, the lower atmosphere preventing too much of either light or heat from reaching them.

The most important result connected with modern researches on the solar spots is due to Schwabe, a German astronomer, who, by perseveringly observing the sun on every day that he was visible between the years 1826 and 1856, finally discovered that the number visible on the disc in the course of a year is subject to a periodic variation, passing through the cycle of its values in successive intervals of about eleven years. Shortly afterwards M. Lamont, Director of the observatory at Munich, discovered that the diurnal variation of the magnetic needle is subject to a corresponding period of equal duration. The researches of Schwabe have been confirmed by Mr. Carrington and other recent observers of the solar spots. Professor Wolf of Zurich, having carefully compared all the recorded observations of the spots, has also discovered unequivocal evidence of the existence of a law in the frequency of their appearance on the solar disc. The duration of the period, as might be expected from the imperfect nature of the observations, is found by Professor Wolf to be subject to considerable irregularities, but on the whole, the observations plainly indicate a recurrence in successive cycles of nearly the same number of spots visible on the disc in the course of a year. The following table, constructed by Professor Wolf from the recorded observations of the spots, exhibits the relative number of spots visible during each of the last 112 years:—

Year.	Relative Number of Spots Visible.	
1749	63·8	
1750	68·2	Maximum.
1751	40·9	
1752	33·2	
1753	33·1	
1754	13·8

A telescope of six inches aperture has been recently fitted up by the Royal Society, at the Kew Observatory, under the superintendence of Mr. De la Rue, for the purpose of taking daily photographic delineations of the sun's surface. The experiment has been attended with complete success, and important results may be expected from the comparison of a series of such records.

The origin of the heat and light of the sun is one of the most obscure points of astronomy. The most recent speculations on the subject are due to Professor William Thomson of Glasgow, who supposes a zone of meteors to circulate around the sun, within the orbit of Mercury, and to be falling gradually upon his surface in consequence of the resistance offered to them by the solar atmosphere. According to this theory, the solar light and heat are generated by the mechanical impact of the meteors on the sun's surface. The existence of a solar atmosphere may be considered to be established beyond all doubt by the corona seen during total eclipses of the sun, and by the fact, that the red prominences seen on such occasions have been observed in several instances to be *isolated* from the moon's limb. That these prominences are solar and not lunar phenomena has been satisfactorily proved by the numerous observations of the total eclipse of 1860, and more especially by the admirable photographs of the phenomenon taken by Mr. De la Rue with the Kew photo-heliograph at Miranda del Ebro. [Solar Eclipse.]

SUN, ECLIPSES OF. [Solar Eclipse.]

SUNDAY, the first day of the week. [Week.] Besides the name of "Sunday" (*dies solis*), it was called by the early Christians "the Lord's day" (*ἡ ἡμέρα ἡ κυριακή*, *dies dominicus*, or simply *κυριακή*, *dominica*) from its being the day on which the resurrection of Christ took place; and it was kept sacred in commemoration of that event. [Sabbath.] The mode of keeping it appears to have varied with the circumstances of the Christians. In the first ages it is very improbable that they abstained entirely from worldly business, as the time of many of them was not at their own command. They seem, however, as far as it was practicable, to have devoted the day to religious worship. For this purpose they were accustomed to assemble before daybreak; and we may infer from passages in the Acts, Epistles, and in Pliny's celebrated 'Letter to Trajan,' that singing hymns, reading the Scriptures, prayer, preaching, and the celebration of the Lord's supper, formed parts of these services.

We have a few notices of the mode of keeping the Sunday during the first three centuries. As early as the end of the second century, abstinence from worldly business seems to have been customary. (Tertullian, 'De Orat.', c. 23.) It was accounted a day of rejoicing, a feast and not a fast, and to fast upon this day was deemed unlawful. Upon it the Christians prayed standing, instead of kneeling, to intimate the elevation of their hopes through their Lord's resurrection. The public worship of the Christians on the Sunday in the first two centuries is described by Justin Martyr ('Apolog.'), whose account is particularly interesting, and by Tertullian ('Apolog.', c. 39; compare Euseb., 'Hist. Ecc.' iii. 3, and iv. 23).

As soon as the Christian religion came to be recognised by the state, laws were enacted for the observance of the Sunday; Constantine (in 321) ordered the suspension of all proceedings in the courts of law, except the manumission of slaves, and of all other business except agricultural labour, which was allowed in cases of necessity ('Cod. Justin.', iii., tit. 12, § 2, 3; 'Cod. Theodos.', viii., tit. 8, § 1, 3); and, as Eusebius tells us ('Vit. Const.,' iv., 18, 19, 20), he forbade all military exercises on Sunday. The laws of Constantine were repeated by subsequent emperors, with additions, of which one of the most important is that of Theodosius II. (in 425), by which the games and theatrical exhibitions were forbidden on Sunday. ('Cod. Theodos.' xv., tit. 7, § 1, 5.) The most strict of these laws is that of Leo and Anthemius. (460, 'Cod. Justin.', iii., tit. 12, § 8.) It should be observed that the provisions of most of these laws extend to all the principal sacred days observed by the Church.

In all Christian communities the Sunday has been observed with more or less strictness, the degrees of which seem to depend on three different views which are held respecting its character. Some regard all the provisions of the fourth commandment as extending to it, admitting however an exception in the case of "works of necessity and mercy;" others agree with these in abstaining from worldly business and amusements, because they think that only thus can the mind be fitted for the religious services which are observed on this day; while others, viewing it as a day of rejoicing, a Christian festival, devote a part of the day to religious worship, and the remainder to recreation. To these views ought to be added a fourth, which, though never adopted, we believe, by any church, has been the opinion of many eminent theologians, namely, that there is no divine authority for making a distinction between Sunday and other days. The whole subject has been fully examined by Dr. Hessey in his 'Bampton Lecture—Sunday, its Origin, History, and Present Obligations,' 1860.

SUNDAY, the first day of the week, a day kept holy by Christians. The common law is silent as to the observance of Sunday, and it seems once to have been the practice not only to exercise worldly callings on that day, but also especially to devote some part of it at least to sports and pastimes, such as now prevail in continental countries, both Protestant and Roman Catholic. This practice continued till some time after the Reformation. Plays are said to have been performed on Sundays at the court of Elizabeth, and even of Charles I. The first restriction that appears among the printed statutes is by the 27 Hen. VI., c. 5, which enacts that all fairs and markets held on Sundays shall cease (the four Sundays in harvest excepted), on pain of the forfeiture of the goods exposed for sale. Immediately after the Reformation in England the legislature regulated the observance of Sunday. The first statute relative to the subject, the 5 & 6 Ed. VI., c. 3, recites that there is not any certain time, or definite number of days, prescribed in Scripture to be kept as holy-days, but the appointment of them is left to the Church, to be assigned in every country by the discretion of the rulers and the ministers thereof. The statute proceeds to enact that certain days mentioned, such as Christmas Day, Good Friday, &c., and all Sundays in the year, shall be kept holy-days; but it provides that in harvest, or any other time when necessity shall require, any kind of work may be done upon those days. No penalty is attached to the infringement of this Act. It is said to have been drawn up under the inspection of Cranmer. By the 1 Eliz., c. 2, all persons having no lawful or reasonable excuse to be absent, are to resort to their accustomed parish church or chapel on Sundays, or to forfeit twelve pence, which was recoverable before justices. The party so offending is also made amenable to ecclesiastical censure, but is only liable to one punishment, be it ecclesiastical or civil. Soon after this time the Puritans and other strict religionists attained political influence. Entertaining a greater predilection for the history and economy of the Jews, as contained in the Old Testament, than had hitherto been exhibited in the Christian world, they began to style Sunday, a term which they thought profane, as derived from Saxon idolatry, the "Sabbath," or "The Lord's Day," names which are not used in the statutes previous to that period. In accordance with this mode of thinking, they seem to have been of opinion that the Christian Sunday ought to be observed in the same manner as the Jewish Sabbath. It was with a view to counteract such opinions, that, in 1618, James I. wrote his 'Book of Sports,' in which he declares that dancing, archery, leaping, vaulting, May-games, Whitsun-ales, and morris-dances were lawful, and that no such honest mirth or recreation should be forbidden to his subjects on Sundays after evening service. The 'Book of Sports' was re-published by Charles I. in 1638. (5 'Harleian Miscellany,' 75.) The Puritans, however, becoming the stronger party, their opinions prevailed, and there followed a rapid succession of enactments in furtherance of them. But the most important statute on the subject is 29 Chas. II., c. 7, which enacts (sect. 1) that no tradesman, artificer, workman, labourer, or other person whatsoever, shall do or exercise any worldly labour or business or work of their ordinary callings on the Lord's day (works of necessity and charity only excepted); and it prohibits the sale and hawking of wares and goods. Sect. 2 prohibits drovers, horse-coursers, waggoners, butchers, higglers, and their servants from travelling, and the use of boats, wherries, lighters, or barges, except on extraordinary occasions. By sect. 3 the dressing of meat in families, the dressing and selling it in inns, cook-shops, or victualling-houses, and crying milk before nine and after four, are excepted from the operation of the Act. By sect. 6 persons are prohibited from serving or executing any process, warrant, &c. (except in cases of treason, felony, or breach of the peace), on the Lord's day: the service, &c., is made void, and the person serving it is made liable to damages, as if he had acted without any writ, &c.

By the 10 & 11 Will. III., c. 24, mackerel are permitted to be sold before and after divine service on Sundays, and forty watermen are allowed to ply between Vauxhall and Limehouse. The 21 Geo. III., c. 49, enacts that no house, &c., shall open for any public entertainment or amusement, or for publicly debating on any subject on Sundays.

The 7 & 8 Geo. III., c. 75, repeals that part of 29 Chas. II. which relates to travelling by water. By 34 Geo. III., c. 61, bakers are enabled, between nine and one o'clock on Sundays, to bake for persons things which are brought to their oven. By 1 & 2 Will. IV., c. 22, drivers of hackney-carriages may ply, and are compellable to drive on Sundays. The 3 Will. IV., c. 19, empowers the court of aldermen, or two justices, to regulate the route of stage-carriages, cattle, &c., on Sundays. These two statutes relate to London only. The 3 & 4 Will. IV., c. 31, provides that the election of corporate officers, &c., required to be held on any particular day, shall take place on Saturdays or Mondays, when the day specified in the Act happens to be a Sunday.

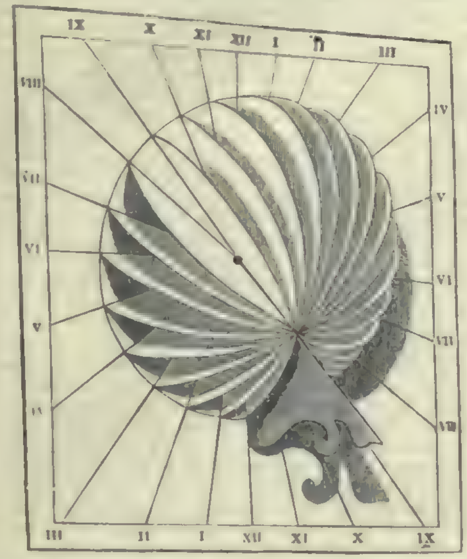
Under these enactments the courts have determined that a contract or sale which, though made on Sunday, is not in the exercise of the ordinary calling of the parties, is valid. Thus a contract of hiring between a farmer and a labourer, and a bill of exchange drawn on a Sunday, have been held to be good. The owner of a stage-coach is not included within the provisions of any of the statutes on the subject; the words "other person whatever," in 29 Chas. II., being restricted in application to persons of the same classes as those enumerated by name. An action, therefore, may be maintained against him for neglecting to take a passenger. Only one offence can be committed by the same party against the provisions of 29 Chas. II., c. 7, by exercising his ordinary calling on a Sunday. Several statutes regulate the hours within which public-houses and other places of refreshment may be kept open on Sunday, the regulation thus made being enforceable by penalties summarily recoverable before magistrates.

SUNDAY SCHOOLS. [SCHOOLS.]

SUNDIAL. Up to a comparatively recent period the science of constructing sundials, under the name of Gnomonics, was an important part of a mathematical course. As long as watches were scarce, and clocks not very common, the dial, which is now only a toy, was in actual use as a timekeeper. Of the mathematical works of the 17th century which are found on book-stalls, none are so common as those on dialling. All that is now necessary is to give some idea of the principles on which such instruments are constructed, as an illustration of a leading fact in astronomy. If a person were to place a staff in the ground, so as to point either vertically or otherwise, and to watch its shadow at the same hour, on different days at some intervals from each other, marking its direction at each day's observation, he would in all probability find that the direction of the shadow, the hour being always the same, varied from day to day. He might, however, find that the shadow was always in one direction at the same hour, and this might happen in two different ways. First, he might by accident fix the staff in a direction parallel to that of the earth's axis, in which case the direction of the shadow would always be the same at the same hour, at all times of the year, and for every hour. Secondly, having fixed the staff in a position not parallel to the axis of the earth, he might happen to choose that particular hour, or interval between two hours, at which the shadow of a staff in *that one direction* always points one way. But if, as is most likely, he were to fix the staff in a direction which is not that of the earth's axis; and if, as is again most likely, he were to choose any time of observation but one, the shadow would certainly point in different directions at different periods.

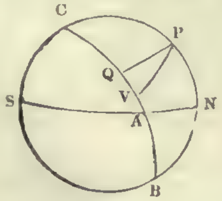
A sundial consists of two parts: the *style*, which is the staff above mentioned, usually supplied to the edge of a plate of metal, always made parallel to the earth's axis, and therefore pointing towards the north; and the dial, which is another plate of metal, horizontal or not, on which are marked the directions of the shadow for the several hours, their halves and quarters, and sometimes smaller subdivisions. In the accompanying diagram, the style is seen throwing its shadow between the directions marked IX and X, on the western side, and indicating that it is about a quarter past nine in the morning. But there is one prominent part of the figure which is never seen on a dial, namely, the hour circles, which are represented as all passing through the edge of the style. As the diagram stands, a skeleton globe of hour circles only is made a part of the construction, to assist in the explanation.

Let us suppose the sun to move with an equable motion, so that it shows the same time as the clock. It does not do so in reality, but the consideration of this point belongs to the article TIME. A large sundial is frequently furnished with a table of the correction of sun-time, to turn it into clock-time, engraved on its face; but this is generally soon corroded. Nor is knowledge of the simplest elements of astronomy so widely diffused as to make such a table of any great use. A person who stations himself in any place of resort which has a sundial, will soon find a lounger who looks in amazement at the difference, perhaps a quarter of an hour, between his watch, which he knows to be right, and the shadow. The church-clock and the sun, in both of which he implicitly believes, are at variance, and he is hardly able to resist the melancholy conclusion that his watch has gained or lost a quarter of an hour in a ten minutes' walk. Neglecting the cause of this, which is an irregularity of solar time, and has nothing to do with any particular mode of reading the results, let us suppose that it is nine o'clock in the morning, solar time. This means that the sun is in that hour-circle which belongs to three hours before noon, or is 3 × 15 or 45 degrees from the meridian hour-circle towards the east. The meridian hour circle is that which cuts the plate of the dial in the line XII XII; and the hour-circle in question (the right-hand one of the two which are not shaded) cuts the dial-plate in IX IX. Now when the sun is in the continuation of any plane, the shadow of that plane is only that of the edge presented to the sun. The upper edge of the style is common to all the hour-circles; and its shadow is, therefore, for the time, part of that of the hour-circle in which the sun is. Hence at nine o'clock before noon the line O IX will be the shadow of the style, O being at the intersection of the edge of the style and the dial-plate (marked by a large dot in the figure). In the diagram, the day has moved on about a quarter of an hour after the time just described, and the shadow has advanced accordingly. There is in it a trifling error of shading (it was taken from De Parcieux's 'Trigonometry,' a work which is very rich in well-drawn solid figures), which will serve to illustrate the subject. The time being between nine and ten o'clock, the sun ought to be looking directly into the crevice between the hour-circles IX and X, in which crevice there ought therefore to be no shadow; but the crevice which is entirely devoid of shadow is that between the hour-circles VIII and IX, so that the sun is made to tell one story on the north side, and another on the south, of the figure. The reader will easily set this right, and will see that as far as the whole hours are concerned, the crevices themselves might be made to answer the purpose of a sundial.



Though the preceding figure was drawn for a horizontal dial, yet any other plane might be substituted. The objections to a dial are, that the shadow of the style is not sufficiently well defined to give very accurate results, even for ordinary purposes: that refraction, which always makes the sun appear a little too high, throws the shadow a trifle towards noon at all times, that is, makes the time too fast in the morning, and too slow in the evening; and that a correction is always necessary in order to find mean or civil time. Even if the first objection could be got over, the corrections requisite for the two latter would prevent persons in general from making use of the instrument. If the edge of the style be not very narrow, it is necessary to have the morning and evening halves of the dial separated by the breadth of that edge.

Those who understand spherical trigonometry will easily see that the general problem of a sundial consists in that of finding out where the hour-lines cut a given circle, as follows. Let BQC be the circle in which the plane of the dial produced cuts the heavens, and let the angle CAS, which it makes with the horizon (h), and CBN, which it makes with the meridian (m), be given. From P, the pole, draw QP perpendicular to the plane of the dial; and the line joining P with the centre being the continuation of the style, that joining the centre with Q is the continuation of what is called the *substyle*. Now in the right-angled triangle ANB, we have



$$\cos \mathrm{NB} = \frac{\cos h}{\sin m},$$

whence NB is found; to which add the latitude of the place, PN, and PB is found. The equations

$$\tan \mathrm{PB} \,.\, \cos m = \tan \mathrm{QB}, \quad \sin \mathrm{PB} \,.\, \sin m = \sin \mathrm{PQ}$$

show how to place the substyle with respect to B, the point answering to noon; and also how to place the style with respect to the substyle. To find the point V at which any given hour-line, PV, cuts the circle CB, first find the angle QPB from

$$\cot \mathrm{QPB} = \tan m \,.\, \cos \mathrm{PB};$$

and VPB, the hour-angle from noon of the sun (V being a point in the shadow). The difference of these angles, QPV, or their sum, is then known; and QV is found from

$$\tan \mathrm{QV} = \tan \mathrm{QPV} \,.\, \sin \mathrm{PQ}$$

It will be better for the beginner to verify these steps on a correctly drawn figure, or to modify them, than to make purely algebraical alterations. Also it is to be remembered that the position of the dial may require both sides of it to be graduated, and the style to extend in both directions, to suit all times of the year and all hours of the day.

SUNNAH. This is the name given by the Mohammedans to the traditionary portion of their law; which was not, like the Korán, committed to writing by Mohammed, but preserved from his lips by his immediate disciples, or founded on the authority of his actions. It holds in Mohammedan theology the same place as the Mishna in the Jewish doctrine, and the names agree in their derivation. The orthodox Mahommedans called themselves Sunnites, in distinction to the various sects which are comprehended under the term Shiites, whose distinguishing characteristic is that they recognise as lawful kalifs Ali and his descendants. The Turks as a nation are Sunnites, and the Persians Shiites. Shiah, from which this latter name is derived, signifies a party or troop.

SUPERCARGO. [SHIPPING, SHIPS.]

SUPERFICIES, the Latin form of the word surface, used in the sense of surface, and sometimes of area. The quantity of an area is called its superficial content, as distinguished from linear content or length, and solid content or bulk.

SUPERPHOSPHATE OF LIME. [CALCIUM, *Superphosphate of Lime.*]

SUPERSEDEAS, in law, the name of a writ used for the purpose of superseding proceedings in an action. In its more general sense it is used to express that which supersedes legal proceedings, although no writ of supersedeas may have been used for that purpose. Thus if a writ of certiorari be delivered to an inferior court for the purpose of removing a record to a superior court, the writ of certiorari is said to be a supersedeas of the proceedings before the inferior court.

SUPPLEMENT (Trigonometry). The defect of an angle from two right angles. Also chords or arcs of a circle or other curve which have a common extremity, and together subtend an angle of two right angles at the centre, are sometimes called supplemental chords or arcs.

SUPPLY. [PARLIAMENT.]

SUPPURATION. [ABSCESS; INFLAMMATION.]

SUPRALAPSARIANS. In the discussions of the doctrines of predestination and election, which arose out of the teaching of the school of theologians at Geneva, two different views came to be taken by the Calvinistic party. Some held that all the occurrences which take place on the earth have been from eternity the subject of a special decree of God: that God decreed to create man solely for his own glory, and to display his glory in the eternal happiness of some and the damnation of others: that this decree respected not merely the end, but all the means, direct or indirect, by which that end was to be wrought out; and that sin, the fall of man, and the introduction of evil into the world, were decreed by God to happen as necessary means to the end proposed, and God therefore so constituted man, and placed him in such circumstances, that he could not but fall. The persons who held these views were called *Supralapsarians* (*supra lapsum*), because, according to their system, the decrees of God respecting the salvation of some men and the rejection of others were in no sense consequent or dependent upon the foreseen fall of man, which itself (on the contrary) took place in consequence of a divine decree.

The other party were called *Infralapsarians.* They considered the decrees of God for fixing the eternal state of man as equally eternal and unchangeable, but they maintained that God did not create man in order that he might fall, but left him free to act for himself; and, though foreseeing that he would fall, did not interfere to prevent him, but decreed that the consequences of this foreseen fall should result in increased glory to himself, and the eternal happiness of the greater part of men.

The synod of Dort adopted the views of the Infralapsarians. Modern Calvinists, generally, go no farther than Infralapsarianism, and often not so far.

SUPREMACY is a term used to designate supreme ecclesiastical authority; and is either papal or regal. Papal supremacy is the authority, legislative, judicial, and executive, exercised until nearly the middle of the 16th century by the pope over the churches of England, Scotland, and Ireland, as branches and integral parts of the Western or Latin church, and which continues to be exercised *de facto* over that portion of the inhabitants of those countries who are in communion with the church of Rome. The extent of the legislative authority of the pope was never exactly defined. Whilst it was regarded as nearly absolute at Rome and at Madrid, it was, at Venice, and still more at Paris, sought to be reduced within very narrow limits.

The papal supremacy was abolished by the legislatures of the three kingdoms in the 16th century. In order to ensure acquiescence in that abolition, particularly on the part of persons holding offices in England and Ireland, an oath has been required to be taken, which is generally called the oath of supremacy, a designation calculated to mislead, it being in fact an oath of *non*-supremacy rather than of supremacy; since, though in its second branch it negatives the supremacy of the pope, it is silent as to any supremacy in the crown. This oath was therefore taken without scruple by persons who were not Roman Catholics, whether members of the Anglican church or not. Roman Catholics might take an oath in which the *civil* and *temporal* authority of the pope were abjured. By the 21 & 22 Vict. c. 48 (1858), the oath was abolished, and another substituted which only pledges the person taking it to temporal allegiance to the sovereign, and repudiates the jurisdiction of any foreign power, spiritual or temporal, of whatever nature it may be.

Regal supremacy is not legislative, but judicial and executive only. Henry VIII. was first acknowledged as supreme head of the church by the clergy in 1528. This supremacy was confirmed by parliament in 1534, when, by the statute of 26 Henry VIII., c. i., it was enacted that "the king our sovereign lord, his heirs and successors, kings of this realm, shall be taken, accepted, and reputed the only supreme head in earth of the Church of England, and shall have and enjoy, annexed to the imperial crown of this realm, as well the style and title thereof, as all honours, dignities, pre-eminencies, jurisdictions, privileges, authorities, immunities, profits, and commodities to the said dignity of supreme head of the same church belonging and appertaining; and shall have power from time to time to visit, repress, redress, reform, order, correct, restrain, and amend all such errors, heresies, abuses, offences, contempts, and enormities, whatsoever they be, which, by any manner of spiritual authority or jurisdiction, may lawfully be reformed, repressed, ordered, redressed, corrected, restrained, or amended, most to the pleasure of Almighty God, the increase of virtue in Christ's religion, and for the conservation of the peace, unity, and tranquillity of this realm; any usage, custom, foreign laws, foreign authority, prescription, or any other thing to the contrary notwithstanding."

SURD. This word has been used to signify an IRRATIONAL arithmetical or algebraical quantity since the time of the introduction of algebra into Europe; though why any term formed from *surdus* was used in such a sense is not known; perphaps it was the supposed translation of an Arabic term. In the article just cited we have said as much as is necessary on the subject. We will only add that the second volume of Cossali's 'History of Algebra' contains an account of the tenth book of Euclid, with reference to the use made of it by the earlier algebraists.

SURDITES. [DEAFNESS.]

SURETY. A surety is one who undertakes to be answerable for another, who is called his principal. Such undertaking must be in writing, and it may be either by bond or by simple writing. A contract is not binding in law, unless made upon some sufficient consideration; but in the case of a bond this consideration is inferred from the circumstances of deliberation incident to its execution as a deed. When the undertaking is not by bond, it is necessary that the consideration should be capable of proof, and that the instrument should be signed by the party who becomes the surety. The instrument however may consist of several writings, if they are so connected by reference to each other that they can be considered as incorporated. The instrument by which the surety becomes bound, when it has reference to civil matters, is generally called a guarantee, and ordinarily consists of an undertaking to become answerable for the payment of goods furnished to the principal, or for his integrity, skill, attention, and other like matters. In such cases the consideration would probably be the furnishing of the goods to the principal, or his employment by the party guaranteed. In the construction of guarantees the same rule of law prevails as in the case of all written instruments,—that they shall be understood in the sense most unfavourable to the party making them which the words will reasonably bear. The application of the rule is very frequent in cases of guarantee where the question arises whether or not the guarantee is what is called a continuing guarantee. Thus where the surety undertakes to be answerable to the amount of 100*l.* for goods supplied to his principal, this may mean that he will be answerable for the first 100*l.* worth, and cease to be answerable for any goods supplied afterwards; or, that he will continue to be answerable to the amount of 100*l.* for any indefinite period during which goods may be supplied, although the principal has paid for the first 100*l.* worth. The latter kind of guarantee is called a continuing guarantee. Observations of a similar character may be made as to the application of payments by the principal.

The circumstances connected with the relative position of the guaranteed and the principal are considered as embodied in the contract between the guaranteed and the surety, and as forming part of that upon which the undertaking of the latter is founded. If, therefore, these are substantially varied, so as to increase the risk of the guaranteed, or to destroy or suspend his remedy against the principal, the surety is thereby discharged. Thus, if the guaranteed has, at the time the guarantee is given, a lien upon property of the principal in his hands, which he afterwards parts with; or if he extends the time of credit, or after commencing an action against the principal gives him time, the surety will be released. But the variation of circumstances must be substantial; a change which does not operate so as to increase the risk or lessen the remedy will not have such an effect. Neither can the surety discharge himself by a mere request or caution to the guaranteed to abstain from trusting the principal, or to watch his acts, &c. Nevertheless it is the duty, and perhaps an implied undertaking, on the part of the guaranteed, against the consequences of the neglect of which a court of equity might relieve the surety, to employ a reasonable degree of prudence and attention in intrusting his goods, or inspecting and checking the accounts of his clerks or servants. The surety is entitled to the benefit of all the securities which the guaranteed has against the principal.

With respect to the rights of the surety against the principal, Mr. Justice Buller has distinctly laid down the law, "wherever a person gives a security by way of indemnity for another, and pays the money, the law raises an assumpsit," that is, implies a promise on the part of the principal to repay to the surety all the money that he has expended on his behalf, and this money may be recovered in an action against the principal for money paid to his use. But in no case is the surety entitled to more than an indemnity from his principal. Thus, if the guaranteed is content with a less sum from the surety, instead of exacting the full amount for which he is liable, the principal will be bound to repay to the surety the less sum only. If the surety has himself taken a bond or other security from the principal, he relinquishes his right to bring an action upon the promise implied in law, and must have recourse to an action upon his security.

Where more persons than one become sureties for the same principal, they are called co-sureties. If one of these has paid the whole of the debt due from the principal, he may recover in an action of assumpsit from his co-sureties the amounts for which they were respectively liable. A court of equity will also interfere to regulate the proportions partly due from each. And in case any of them are unable to pay from insolvency, &c., it will compel the others to contribute proportionally the amount for which the defaulters were liable. The law is the same as to co-sureties, whether all have been created by the same instrument in writing, or each one by a distinct instrument.

SURETY OF THE PEACE is the acknowledging of a recognisance or bond to the crown, taken by a competent court for keeping the peace. Magistrates have the power to take such recognisances, which are generally done by the party acknowledging (*recognising*, and hence the term *recognisance*) that he is indebted to the crown to a certain amount, the condition of which bond is, that he or the party for whom he becomes bound shall keep the peace during a term named in the condition. Such recognisance may be obtained by any party from another on application to a magistrate, and stating on oath that he has just cause to fear that such other "will burn his house, or do him a corporal hurt, as by killing or beating him, or that he will procure others to do him such mischief." Upon such application being made to the magistrate, it is his duty to summon the party before him and cause him to enter, either alone or with others, into such recognisances as he thinks the case demands. The fear must be of a present or future danger: no recognisances are demandable on the ground of a past offence. Upon the neglect or refusal of the party so summoned to enter into the recognisances demanded, he may be committed to prison by the magistrate for a specified period, unless he sooner complies. If the recognisance is forfeited by a breach of the condition, it may be removed into one of the superior courts and there proceeded upon.

Sureties also may be similarly required for the good behaviour of parties who have been guilty of conduct tending to a breach of the peace, abusing those in the administration of justice, &c.

SURFACE, SURFACES, THEORY OF. For the mere definition of surface, see SOLID, &c. We are here to speak of that branch of algebraic geometry which considers the generation and properties of curve surfaces following an assigned law.

If three planes, each at right angles to the other two, be taken as the planes of CO-ORDINATES, the position of any point is determined so soon as its co-ordinates, or distances from the three planes, are given in sign and magnitude. If the co-ordinates of a point be x, y, z, and if between these one equation exists, $\phi(x, y, z)=0$, any point may be chosen in the plane of x and y, by means of given values of x and y, and the corresponding value or values of z may be found from the equation. The locus of all the points whose position can be ascertained by determining one of the co-ordinates from this equation, the other two being taken at pleasure, is a surface of which $\phi(x, y, z)=0$ is called the equation, and the modes of proceeding are pointed out in all works on algebraic geometry. The applications of the differential calculus depend on the principles explained in TANGENT: the graphical use of the whole method depends mostly on descriptive geometry, whether formally known under that name or not.

Surfaces are distinguished algebraically by the nature and order of their equations. Thus we have surfaces of the first order, in which the equation is of the first degree (this class contains the plane only); surfaces of the second order, which will be classified in the next article; and so on.

Surfaces are also distinguished by their mode of generation, and some of the principal cases are as follows:—

1. *Cylindrical surfaces* are generated by a straight line infinitely produced in both directions, which moves so as always to be parallel to a given line, and to have one of its points on a given curve.

2. *Conical surfaces* are generated by a straight line infinitely produced in both directions, which always passes through a given point or vertex, and has one point in a given curve. The common CYLINDER and CONE would be described in this science as a *right circular cylinder* and a *right circular cone*. The cylindrical surfaces themselves are only an extreme case of the conical ones, being what the latter become when the vertex is removed to an infinite distance.

2. *Surfaces of revolution* are generated by the rotation of a curve about an axis, relatively to which it always retains one position. The common cone and cylinder, the SPHERE, and others of the greatest practical use, are contained in this class.

4. *Tubular surfaces* are generated by a circle of given radius, which moves with its centre on a given curve, and its plane at right angles to the tangent of that curve. When the given curve is a circle, the tubular surface is a common ring.

5. *Ruled surfaces* (the *surfaces réglées* of the French writers) are those which are described by the motion of a straight line, which neither remains parallel to a given line nor always passes through a given point. This includes, among many others, the whole class of *conoidal surfaces*, made by a straight line which moves parallel to a given plane, and always passes through a straight line perpendicular to that plane, and also through a given curve. The surface of a spiral staircase, as it would be if there were no steps but only a gradual ascent, is an instance.

6. *Developable surfaces* are those which can be unwrapped on a plane without any doubling of parts over one another, or separation; that is, without being rumpled or torn. The only familiar instances are the cylinder and cone.

SURFACE OF ELECTRICTY. [POLARIZATION OF LIGHT.]

SURFACE OF THE EARTH. Geology, by teaching us to look upon the form and distribution of land and sea, the features of hills and valleys, and the various deposits of peat, silt, gravel, &c., as effects of physical agencies, some of which are no longer in operation upon those areas where once they predominated, confers upon the surface of the earth an interest much greater than that which belongs merely to pictorial combinations, or even to agricultural utility and commercial adaptation. Uniformity, inequality, height, depth, and area, every the least peculiarity of form, whatever is remarkable in any part of the surface of the land or bed of the sea—these are effects of causes which require to be traced out before the problem of the physical history of the globe can be considered as resolved. Geology was pronounced by Sir C. Lyell, early in his career of research, to be the science of surfaces.

Superficial Deposits. If the stratified and unstratified rocks which compose the skeleton of the earth were laid bare to our view, the aspect of the globe would be far more rugged than it is now. The valleys would in many cases lose their soft and easy curvatures and accordant slopes, in angular fractures and irregular chasms; the mountains and hills would lose those sloping buttress-like banks, composed of fallen materials, which connect the broken ridges above with the level expanse below; a sterner aspect would belong to the now sinuous lines of sea-coast; and an almost general barrenness would overspread the inland surface.

The soil, gravel, clay peat, and other substances, which by their accumulation mask the features of the interior rocks, constitute a peculiar class of phenomena which have been much, and yet not sufficiently, studied by geologists. It is certain that without a more exact appreciation of the causes which have permitted the aggregation of the "superficial deposits" already named, our analysis of the processes whereby the earth has been made fit for the residence of man, and adapted to its present uses, must be very imperfect.

Soil is often supposed to be merely the disintegrated parts of the subjacent rocks, and this is sometimes really the case; trap rocks, for example, of which the felspar and the hornblende become decomposed by the atmosphere, yield a soil often remarkable for fertility, and uncontaminated with foreign ingredients. But the soils which cover clays and limestones and sandstones are seldom of this simple origin. The bases of these soils may be generally derived from the subjacent strata, but they usually contain foreign ingredients. The soil on the chalk and limestone hills of England is often sandy, sandstones are covered by loam, and clays overspread with pebbles. The effect of this admixture of foreign substances with the disintegrated parts of the native rock is usually favourable to fertility.

We may often understand the cause of these admixtures by considering the effect of rains and currents of water on the sloping surface of the earth. These effects arrive at a maximum in particular vales and plains, into which many streams enter after flowing over strata of different kinds. In such vales the soil is in fact a mixture of calcareous, argillaceous, and arenaceous parts, and its indigenous plants are correspondingly varied, and include many which are not found growing together on any one of the soils which are here mixed together. [SOIL.]

To watery agency, acting under the actual circumstances of physical geography, we may also ascribe many even extensive accumulations of gravel and sand which lie along the sides of valleys and in hollows of hills, or on the slopes of mountains; and it requires sometimes only the postulate, that in particular valleys inundations have formerly reached higher levels than at present, to apply the same explanation to terraces of gravel and sand now considerably above the actual flood-mark, but sloping parallel to the general inclination of the valley.

The beds of old lakes, often consisting of layers of shelly marl, with bones of existing or extinct quadrupeds, the surfaces of silt which lie along the actual and ancient æstuaries of rivers, and often conceal buried forests and subterranean peat, present no difficulty as to their origin. For the processes by which peat grows and trees are buried, and marshy land is saved from the sea, and lakes are filled up, are at this day in action. To all such peat or turf moors, subterranean forests, marsh and fen land, drained lake-beds, and sand and gravel, the title of *alluvial deposits* is very commonly given. Generally, they require no supposition of extensive changes of physical geography produced by violent disturbances of nature, but seem to be clearly and perfectly explicable by causes still in action, though perhaps not in the same situations on the earth's surface. But there are other gravels, sands, and clays, to which this explanation cannot be applied without calling in aid great changes of physical geography, or physical processes not seen in daily operation; such as extensive displacement and change of level of land and sea; unusual floods of water; surprising alterations of climate, or movement of glaciers in situations where now the snow and ice of the coldest winter melt with the first breath of spring. These phenomena were classed under the title of *diluvial deposits*, at a time when their origin was very generally ascribed to violent floods of water, and the title was retained even by geologists who did not admit this hypothesis. They are now generally included by geologists under the designations of boulder-clay, boulder formation, and northern drift; the latter term having been applied to them, because, in Europe and in North America, where only they have yet been distinctly recognised, they have evidently been brought from regions to the north of those in which they are now found. At the same time, according to Sir C. Lyell, "the bulk of the mass in each locality consists of the ruins of subjacent or neighbouring rocks; so that it is red in a region of red sandstone, white in a chalk country, and gray or black in a district of coal or coal-shale." They belong both to the newer pleiocene or pleistocene and to the post-pleiocene series of present geological nomenclature.

These so-called diluvial deposits are commonly admitted or assumed to be of older date than those called alluvial, and, taken in a collective sense, they are so, but this is the least important circumstance characteristic of their history. The conditions of their accumulations are remarkable.

1. It is often seen that thick deposits of clay, sand, and pebbles, or large fragments of rock, lie on the very summits of hills (as abundantly on the hills which adjoin the valley of the Thames).

2. Fragments of rocks quite unlike those of the vicinity lie in valleys, on hills (as on the Salève near Geneva), and even on islands (as on Staffa).

3. These fragments are found solitary, or buried in clay, sand, or gravel, and sometimes in enormous abundance, as in Huntingdonshire, near Birmingham, in Holderness, and other parts; and they are such that no stones of like nature occur anywhere in the natural drainage of the country where the gravel is accumulated, nor within 20, 50, or even 100 miles of the spot.

4. The fragments (often called boulders, and also erratic blocks) appear thus in several cases to have been transported from particular parts of the country, over elevated ground, across the natural valleys and ranges of hills, but yet are, in some cases, distributed in a manner

which manifests a decided dependence on some of the greater features of physical geography. Thus the abundantly spread detritus from the Cumberland mountains crosses the island to Tynemouth, and reaches the coast of Yorkshire, but does not cross the Pennine chain of mountains, except at one point (Stainmoor), though it spreads along the western side of it as far south as Manchester and the plains of Cheshire and Staffordshire. In like manner the detritus from the Western Alps has been carried on to the Jura, and lies in a strange manner in all parts of the hollow of the Lake of Geneva, and on the insulated Salève Mountains; yet it has been observed that the lines followed by the boulders are those of the great valleys, so that each great valley has been the direction in which were carried the blocks from the head of that valley.

5. It is observed that often the largest blocks contained in a mass of this detritus lie at the top, resting on the smaller gravel and sand; and that below the whole mass the hard rocks are scratched by parallel distinct small grooves or striæ, marks of the dragging movement to which the stones were subject in their passage.

6. Though in some cases successive deposition can be traced in the parts of such a mass, it is very often seen that the materials are entirely unarranged, mere heaps of stones, and sand or mud; the stones being often indiscriminately stuck in clay, large and small, heavy and light, absolutely without any stratification, such as long suspension in water must certainly have produced.

7. Finally, amidst such confused masses, bones of land quadrupeds, mostly or entirely of extinct species, and even of extinct genera, occur, and locally even in abundance. These are, however, more common in laminated lacustrine deposits resting upon the diluvial masses, or perhaps covered by them.

With the mammalian remains alluded to are not unfrequently associated, as has recently (1861) been shown, flint implements of human work; indicating, if not proving, the contemporaneity of some of the now and long since extinct mammals with certain races of man. (Prestwich, in 'Phil. Trans.,' 1860.)

It was thought possible to explain these characteristic phenomena by many local inundations, or one general and overwhelming flood, capable of overcoming many of the lesser inequalities of surface-level, but modified in its course by the larger ranges of mountains and valleys. And as in the northern zones of the world (which have been much investigated in this respect) there is a very frequently observed direction of the boulders to the south or south-east, it has been proposed for consideration whether some great change of the level of land and sea in the circumpolar regions might account for what seems a general fact. But further, as the most abundant deposits of this nature have been drifted from particular chains of mountains, as the Cumbrian group in England, the primary mountains of Norway, the Alps, &c., all which districts have undergone elevation *at some time*, it has been thought that their upward movement may have been the cause of the displacement and transport of the blocks. (Buckland, 'Reliquiæ Diluvianæ;' Elie de Beaumont, 'Sur les Revolutions du Globe.')

It has, however, been proposed to account for the distribution of the boulders by a more gradual action of the waters of the sea. If the region of Cumbrian rocks, for example, and a very large portion of the north of England, were supposed to be raised from the sea, by a continual or intermitting movement, so as to bring successively under the action of the breakers the whole country to the east and south-east of the area now occupied by the Cumberland mountains, this would allow of a continual drifting of the boulders to the east and south, by the continual tendency of the tides and currents of the sea. (Phillips, in 'Treatise on Geology, &c.;' Whewell in Murchison's 'Silurian System.') Floating ice has been represented as adequate to carry off from the shore where it was formed masses of mud and fragments of rocks, and, by melting or turning over, to spread them on the bed of the sea. This sea-bed raised would show the accumulations from such icebergs, often in narrow bands or insulated patches, such as really occur, and have been long celebrated, among the heaps of Norwegian detritus which lie on the sandy plains of North Germany. (Lyell, 'Principles of Geology,' 'Manual of Elementary Geology;' Murchison, 'Silurian System.')

Finally, ice in another form has been appealed to for the explanation of these phenomena. The formation of glaciers in mountain valleys is such as to permit of their forward movement down a slope, and their carrying with them in their progress fragments of rocks and heaps of gravel and mud which by any cause fall upon their surface. These heaps of "moraine" accumulate along the sides and at the lower termination of the glacier, and the arrangement, or rather confused aggregation, of the materials in them resembles very much that of the masses to be accounted for. The surface of the rocks below a glacier is scratched, as we have before stated to happen in places where boulders are noticed; and as in the Alps it is certain that glaciers have formerly been extended much farther from the mountain-summits than now they are [Snow, Perennial], it has been conjectured that anciently, in the times coincident with or preceding the boulder or drift period, they were very much more extended, so as even to have reached from the Alps to the Jura, from the mountains of Norway to those of Bohemia, and from Shap Fells in Westmoreland to the mouth of the Humber. Upon the subsequent contraction of these glaciers, the moraines they had left would experience some changes by the action of water (melted ice), which might then run in lines impossible for watery currents after the ice was fully removed. (Agassiz, 'Etudes sur les Glaciers.') On the grooves and striæ on the surfaces of rocks Mr. Jukes remarks ('Popular Physical Geology,' p. 280), in considering the former action of ice, here alluded to, "In addition to ice however, Mr. Mallet has acutely pointed out that many of these appearances may be due to what he somewhat inappropriately terms 'mud glaciers,' by which he means the sliding forward or slipping of great masses of clay, mud, or sand, charged with pebbles and boulders, along the inland surfaces of rock, either as the land rose from the sea, or when they were subsequently loosened by the action of rain and other water."

The examination of the boulders of certain parts of the Himalayan range, and the application of the theory of glacier movement to explain their distribution, has led Dr. Joseph D. Hooker to suggest some modifications of that theory in respect of those localities. The banks of the Great Rungeet river, near its junction with the Kulhait, consist of mica-slate, cumbered, in a deep gorge through which the river flows, with enormous boulders of that rock, of clay-slate, and of granite, some fully 10 feet in diameter. But the latter rock is not common at elevations below 10,000 feet, whereas the absolute elevation of the river here is only 1840 feet; it is not easy therefore to account for their present position. "They have been transported," Dr. Hooker infers, "from a considerable distance in the interior of the lofty valley to the north, and have descended not less than 8000 feet, and travelled fully fifteen miles in a straight line, or perhaps forty along the river bed. It may be supposed that moraines have transported them to 8000 feet (the lowest limit of apparent moraines), and the power of river water carried them further; if so, the rivers must have been of much greater volume formerly than they are now." Another explanation was required by the enormous fractured boulders of gneiss frequent over the whole of the mountain Mons Lepcha, in the Sikkim Himalaya, at elevations of from 7000 to 11,000 feet. Contrary to those mentioned above, they were of the same material as the rock *in situ*, and as unaccountable in their origin, by received theory, as the loose blocks on the Dorjiling and Sinchul spurs to the south, at similar altitudes, often cresting narrow ridges. Dr. Hooker measured one angular detached block, 40 feet high, resting on a steep narrow shoulder of the spur, in a position to which it was impossible it could have rolled; "and it is equally difficult to suppose," he observes, "that glacial [glacier] ice deposited it 4000 feet above the bottom of the gorge, except we conclude the valley to have been filled with ice to that depth." A third modification of or addition to the glacier theory of boulder distribution, is pointed to by the locality of the Jongri spur of the great mountain Kinchinjunga [Orology], over which are scattered blocks of gneiss, many 20 feet in diameter. "It is not possible to account for the transport and deposit of these boulders by glaciers of the ordinary form, namely, by a stream of ice following the course of a valley; and we are forced to speculate upon the possibility of ice having capped the whole spur, and moved downwards, transporting blocks from the prominences on various parts of the spur." 'Himalayan Journals,' vol. i., pp. 242, 253, 288.

The entire subject of the transport of erratic blocks, and of the hypotheses which have been framed to account for it, has been critically examined by Mr. W. Hopkins, in a paper 'On the Elevation and Denudation of the District of the Lakes of Cumberland and Westmoreland,' in the 'Quart. Journ. of the Geol. Soc.,' vol. iv.

The great mass of diluvium from the Cumbrian mountains, already alluded to, which covers the surface of Lancashire, rests on nothing more recent than the new red sandstone, and Mr. Hopkins conceives that its transport might have begun with the elevatory movements which disturbed that formation, when the surface of the present mountainous district began to rise permanently above the surface of the ocean, and the valleys began to be formed. The spreading out of diluvial matter—that term being now adopted in its broad physical sense—may be regarded as the necessary consequence of wide general currents, and that this has been the agency by which the mass of diluvium in question has been transported to its present locality and position, does not admit, in Mr. Hopkins's opinion, of the smallest doubt. He accounts for the existence of currents diverging from the centre of the district by a repetition of paroxysmal elevations of from 100 to 200 feet; and, affirming the entire adequacy of this cause to transport all the erratic blocks derived from that region, concludes that such has been the agency by which that transport has actually been effected. He rejects the iceberg theory in its application to the case investigated, but conceives that floating ice may probably have been the most efficient agent in transporting the larger blocks of colder regions from their original localities. Mr. Hopkins's paper may be studied with great advantage with reference to the whole subject of the distribution of boulders and of the northern drift.

We do not propose to investigate any of the hypotheses above stated, preceding the facts and reasoning we have derived from Dr. Hooker and Mr. Hopkins. Geologists have been remarkable for eagerly adopting and as easily abandoning most of them; and others might have been added merely as beacons to be avoided. It may be proper however to point out three things which may be useful to remember in further prosecuting this subject, and which, indeed, have neither been forgotten nor neglected, by the geologist last named.

1. It must be determined by evidence whether the accumulation to be explained happened on the land at its present level, or on the bed of the sea.

2. It must be determined by evidence what was the probable character of the climate in the countries where diluvial accumulations excite attention.

3. In proposing a general cause, such for example as the movement of glaciers, it must be shown to be adequate to satisfy all the minuter details of the phenomena, and not inconsistent with general limiting conditions established by extensive induction from facts observed in the earth itself, or admitted as parts of general cosmical theory. [REFRIGERATION OF THE GLOBE; and, in NAT. HIST. DIV., GEOLOGY and SUBMARINE FORESTS.]

The determination of the cause of the diluvial accumulations is of the highest importance in geological theory. It is impossible to doubt that to the same cause must be ascribed many considerable modifications of the *pre-existent surface* of the land. If, abstracting our attention from the accumulated deposits which conceal the stratified and other rocky masses in the crust of the earth, we look at the *actual form* of its surface, there appears little that is even difficult of explanation by the application of known and real causes. The relative areas of sea and land; the peculiarities of outline of continents and islands; the directions of mountain-ranges, and remarkable vales and plains; the individual features of hills and valleys; the degree in which the land is wasted in some quarters and augmented in others; and the rate of change which may take place in these respects;—all this may be satisfactorily referred to subterranean and submarine disturbances of different periods, to the effects of the sea upon the land when the land was not at its present level above the water, and to the operation of the atmosphere, rains, rivers, and inundations.

From this large field of research we shall select for brief illustration the outlines of land and sea, the directions of high and low ground, and the individual features of hills and valleys. The few examples needed will be drawn from the British Isles, but the explanations are of general application. To render the article, as reproduced in this work, more accordant with the actual state of geology, illustrations of other parts of the subject are now added, some from foreign countries, but of general application equally with the former.

Much of the irregularity of outline, on a large scale, of the British Islands depends on the *form* in which the ancient bed of the sea was elevated into dry land. Thus the line of the Hebrides, the prominent parts of Caithness, of Aberdeenshire, and of Argyleshire, are on axes of upward movement of the primary strata; while the Great Caledonian Valley, from Fort William to Inverness, and the great basin of the Forth and Clyde, are in axes of depression of the strata. This latter hollow is margined on the south by the great axis of elevation of the Galloway and Lammermuir hills, reappearing beyond the Irish Channel south of Belfast, as the Argyleshire chain is resumed in Donegal. The Isle of Man, the promontory of Lleyn in Caernarvonshire, the east and west ridges and hollows of the strata which reach the sea in South Wales and North Devon, give to Pembrokeshire, Glamorganshire, and North Devon remarkable and detailed alternations of promontory and bay. The Isle of Wight is formed on an axis of elevation from the Needles to Culver Cliff; while north of it are the axis of depression of the Solent, the axis of elevation of the wealds of Sussex, and the axis of depression of the estuary of the Thames.

Inland, the same ridges and hollows, and others of as great importance, produce continuous chains of hills, the North-Western Highlands, the Grampians, the Lammermuir range of hills, the Wicklow mountains, the Snowdon mountains, the Berwyn, and Malvern hills, and multitudes of other narrow tracts of elevated land. Great *faults*, elevating or depressing one portion of a natural district, leave marks of inequality on the surface. Thus the great Pennine faults, ranging from Newcastle to Brampton, and thence to Kirby Lonsdale and Settle, occasion differences of level in the ground of 1000 and 2000 feet for a length of 100 miles.

In all cases, and in every country, it appears that, notwithstanding the operation of later agencies, the main features of the surface of the land are due to the positions in which subterranean movements left the displaced masses of rocks. But the operation of subsequent agencies is distinctly traceable in modifications of these features on the sea-coast, and in the interior of every country.

The surface of the land has been *wasted*, and as the various stony and earthy masses which come to the surface have unequal compactness, and are unequally capable of resisting the chemical and mechanical agencies which originate in the varying heat and moisture of the atmosphere, we find in consequence a multitude of irregularities, both on a large and small scale, directly related to the properties of the rocks. On the sea coast some parts are known to be wasted (as the coasts of Sheppey, Dunwich, and Bridlington) even rapidly, one or several yards annually on the average; others seem almost unchanged by a thousand years of storm and tempest, as the "Worm's Head;" and some considerable tracts of new land have been added to the shores of Lincolnshire, along the banks of the Thames, and by the side of the Severn.

The line of coast from the Tyne to the Humber is instructive in this respect. The prominences on the Durham coast, ending with Hartlepool, are guarded by magnesian limestone, and the estuary of the Tees is excavated in red marl and lias clays. The peak near Robin Hood's Bay, Scarborough Castle Hill, Filey Brig, and Flamborough Head, are all promontories of hard rocks; but Robin Hood's Bay, Scarborough Bay, Filey Bay, and Bridlington Bay, are all excavated and wasted in clays of the liassic, oolitic, and diluvial periods. The interior of the country shows similar effects on a grander scale. The great vales and plains of England, in parts the least influenced by subterranean disturbances, are by no means the excavated paths of rivers, nor are the great ranges of hills the separating summits between such rivers. The plains and vales are lines of soft and perishable strata, and the crests which divide these vales are ranges of harder rocks. A transverse section of the English strata shows always, both on a large and small scale, this important fact (see *fig.* 1), and every well-shaded topographical map, coloured geologically, demonstrates the extent of its application in explaining the irregularity of surface. The chalk hills, oolitic hills, &c., alternating with vales of clay, in all the southern and eastern parts of England, give to those parts characters far more important than the undulations connected with river channels.

Fig. 1.

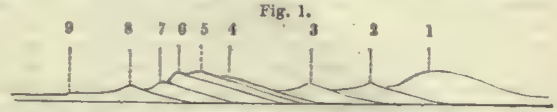


Fig. 1 shows the relatively prominent parts in a line of section across the secondary strata. 1, being chalk; 2, lower green-sand; 3, coralline oolite and calcareous grit; 4, cornbrash; 5, forest marble; 6, great oolite; 7, inferior oolite; 8, marlstone; 9, lias limestone. The intervening hollows are uniformly argillaceous.

Similarly, hills and valleys, in which rocks of unequal power of resisting watery action appear, show the force and continuity of this action by the prominence of the hard rocks and the excavated surfaces of the softer masses. Thus, in *fig.* 2, we see on the breast and edges of a hill composed of limestones, sandstones, and shales, the especial prominence of the limestones; and where these cross a valley, each limestone edge is the place of a waterfall. By studying in such valleys the manner in which the actual stream wastes the rocks, we can easily assure ourselves of the truth of the general explanation offered above. In *fig.* 3 is a section of a waterfall, showing the edge of limestone (*a*) over which the water falls, and under it a bed of sandstone (*b*) little wasted, but at the bottom a body of shale which has perished by the dampness and spray, and is excavated in a remarkable manner.

Fig. 2.

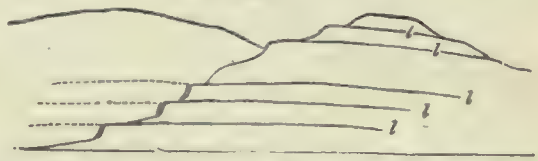

Fig. 2. Aspect of a mountain consisting of carboniferous limestone, shale, and sandstone; the limestone bands (marked *l*) project remarkably, and, where they cross a valley, make waterfalls.

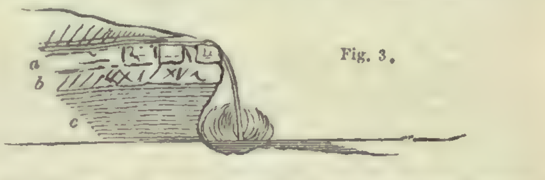

Fig. 3.

Fig. 3. The side view of a waterfall, where the stream falls free of the rock, and causes excavation in the subjacent shales.

Just such an action is observable on similar cliffs by the sea, and in each case the same effect follows: the falling of the hard rock at top from want of support below. Thus the situation of a waterfall is daily displaced, and is moving up the stream, as the Falls of Niagara and Hardrow Force are known to have done. (Lyell, 'Principles of Geology.') Into all these effects of waste on the earth's surface rain enters for something important. Few surfaces of rock are altogether exempt from chemical changes dependent on atmospheric variations; all are more or less liable to perish with rain, frost, and watery movements; and thus the individual features of hills and valleys, the ranges of high and low ground, and the outlines of land and sea, appear to be effects impressed by subterranean movements and fractures of the earth's crust, modified by the action of the sea on materials of unequal resisting power, while they were below, and while they were rising through its waters, and by the subsequent mechanical agencies of rivers, rains, and chemical forces excited by atmospheric variations. [GEOLOGY, in NAT. HIST. DIV.]

Mr. G. Poulett Scrope, M.P., F.R.S., the author of some precious contributions to igneous geology, of the most original kind, but which, after the lapse of more than the third part of a century, are only beginning to be duly appreciated, has urged, in his 'Geology and Volcanos of Central France,' first published in 1826, and in a paper on the excavation of certain valleys, communicated to the Geological Society a few years after, the conclusive nature of the evidence of the immense changes in the surface of the earth which have been effected by the action of "meteoric agents"—that is, of the atmosphere, its depositions, and its ever-varying temperature,—together with that of the streams they produce, upon the different rocks and materials constituting the land, and which, in his judgment, entirely supersede the necessity for referring them to the agency of mighty overwhelming floods and currents, however occasioned. Describing the volcanic formations of the Velay, and in particular the position and actual state of a current of lava, which has spread itself to the width of five, seven, and nine miles, covering an extensive and elevated table-land formerly called the Coiron, which consists of Jurassic or oolitic strata, he shows that there cannot be the least doubt but that the whole of this lofty tract of secondary strata has been solely preserved from destruction by its volcanic capping. The remainder of the oolitic formation around, forming the secondary district of the Rhône valley, has been eaten into in all directions by various mountain torrents, and gnawed down by meteoric abrasion to a far lower level. The immense quantity of matter which must have been thus abstracted from the oolitic mass since the epoch at which this lava was emitted from the now extinct volcano of the Mont Mezen—an epoch proved to be but recent by the fact that, beneath the basalt which it has become, a vegetable soil is found, containing terrestrial shells of a species still existing in the same country—"cannot but strike us with astonishment. There can be no doubt," Mr. Scrope continues, "that the surface on which the basalt of the Coiron rests was at that period the lowest of the neighbouring levels, or these repeated currents of liquid [flowing] matter could not have flowed in its direction; yet at present this same surface vastly overtops every other height of the same formation, and ranges upwards of a thousand feet above the average level of the valley-basins of the Ardêche and Rhône on either side. That a considerable proportion of these was excavated by 'rain and rivers,'—in other words, by meteoric agency such as is still in operation, and not by any diluvial or general flood,—is susceptible of direct proof. To attribute, therefore, the remainder to any other cause of an hypothetical nature unsupported by evidence, would seem to be contrary to the rules of analogy. But the conclusion that the greater portion of the valley of the Rhône has been so recently excavated, and by such agency alone, involves important consequences, since the same agents must have been at work everywhere else, and produced results as stupendous during the same comparatively recent period." ('G. & V. of Central France,' ch. viii.) In the second edition of this work, published in 1858 (ch. ix., pp. 207-208, note), the author expresses his opinion that neither Sir C. Lyell (the most comprehensive advocate for the sufficiency of existing causes) nor the bulk of geologists are "even yet sufficiently impressed with the immense amount of excavation or denudation effected on supra-marine land by the erosive force of the pluvial and fluvial waters." "That story," he adds, "is yet to be written."

There are, however, limitations to these changes in the present condition of the earth's surface, some of which are ultimately imposed upon them by their own operation. They were acutely urged by the late Rev. Dr. W. D. Conybeare, a consummate geologist of his time, in his introduction to the 'Outlines of the Geology of England and Wales,' by himself and the late Mr. W. Phillips, and in some papers in the 'Philosophical Magazine' consequent upon the first appearance of Sir C. Lyell's 'Principles of Geology.' From thirty to forty years have elapsed since the publication of his views, which have been almost forgotten, on which account we cite, from the publication first mentioned, some of the most apposite :—"Over a great part of the earth's surface the influence of these wasting causes is absolutely null, the mantle of greensward that invests it being an effectual protection. The burrows of the aboriginal Britons, after a lapse of certainly little less, and in many instances probably more, than two decades of centuries, retain very generally all the pristine sharpness of their outline; nor is the slight fosse that sometimes surrounds them in any degree filled up. Causes, then, which in two thousand years have not affected in any perceptible manner these small tumuli, so often scattered in very exposed situations over the crests of our hills, can have exerted no very great influence on the mass of these hills themselves in any assignable portion of time which even the imagination of a theorist can allow itself to conceive; and where circumstances are favourable to a greater degree of waste, still there is often a tendency to approach a maximum at which farther waste will be checked: the abrupt cliff will at last become a slope, and that slope become defended by its grassy coat of proof. It should appear that even the action of the sea, certainly the most powerful and important of all those we have surveyed, has a similar tendency to impose a limit to its own ravages." Dr. Conybeare also considers, in relation to the permanence of the general surface of the globe, the possible effect on the level of the sea of the quantity of materials carried into it, which he concludes to be absolutely imperceptible—a conclusion amply justified by the recent investigation of Mr. A. Tylor, as noticed in the article SEA, col. 418.

The relation of these and other limitations to the consequences of the modern doctrine referring the mighty operations which have formed and modified our continents to causes now in action, acting also under their present conditions, and with only their present forces, has not been adequately considered by subsequent geologists. Dr. Conybeare's views on this subject, we conceive, in common with those taken by him on other important points in the philosophy of geology, have not received from his successors the consideration they deserve: a circumstance of which the fact of his own withdrawal from the pursuits of science for many of the later years of his life, may afford some explanation.

The subject of the preceding portion of this article is one of physical geography and geology. But we may regard the surface of the globe in a wider philosophical sense, not as confined to that of the land and sea-bed, but as the limit of the extension of the matter constituting our planet; and therefore, also, of a certain class of the actions which maintain it, though not of all the forces to which that matter is subject, some of them extending beyond that limit. In this sense the earth has two surfaces, that of the land and water taken together, and that of the thin spherical shell of air that rests upon and encompasses it. The latter is the termination in space of our planet; the former, the termination of the solid and liquid matter of which the earth, or at least its superficial crust, consists, whatever may be the physical state of the more central interior, of which we know nothing. These surfaces are the final results of the equilibrium which the mutually acting and reacting forces of nature maintain in the globe.

Thus considered, the subject has an interest of its own, independent of the geographical and geological importance of the surface of the land or solid matter. Though the waters form only a residual film, as it were, of certain materials of the crust which are liquid at the mean temperature of the surface, a result of the final equilibrium of the chemical and physical actions taking place below and above, yet their portion of the surface, so much greater than that of the exposed solid matter, or land, has a paramount influence on the constitution of the terminal shell of matter—the atmosphere—with respect to its aqueous constituent. The atmosphere, in like manner, is the resultant residue of the physical and chemical actions taking place upon the terraqueous surface, or below, within reach of the atmosphere, but consisting of materials which are aëriform at the mean temperature of the globe; some, indeed, at all known temperatures; others within a certain range of them.

The definite surface of the terraqueous globe, there is reason to conclude, is repeated in that of the atmosphere, the finite extent of which we conceive to be demonstrated by that of the column of mercury or water, or other gravitating fluid in the barometer. It would appear, on first considering the subject, that the only changes this surface can undergo will be extensive perpetual undulations of the nature of tides, and disturbances occasioned by the entrance and transit, and perhaps by the ignition, of the bodies which become meteors. It may, however, be true, agreeably to the views of Poisson, in particular respects anticipated by Graham and by Luke Howard, and with which also harmonise certain inferences regarding the structure of the higher regions of the atmosphere originally drawn by Mr. Brayley, and virtually adopted by the late Professor Daniell—that the atmosphere has a terminal film of solid matter—frozen air—forming upon a subterminal one of liquid matter—liquefied air—itself passing below into a stratum of air-vapour, and that into a still inferior one of dense air retaining its gaseous condition; the rarest stratum of the air being thus beneath the summit of the atmospheric column, and not constituting the upper surface, as long tacitly assumed, and as indeed would follow from the law of elasticity of the air considered by itself. In this case, in addition to the movements alluded to, the surface of the atmosphere must be in a state of perpetual equilibrated motion and change, the ultimate physical resultant of the continual subversion and restoration of equilibrium, or at least, of the existing tendencies to those conditions, arising from the antagonism of heat and gravitation.

The complex superficial crust of our planet, of which the surfaces of the atmosphere and of the terraqueous globe are the superior limits, is the final result of the action of the sun upon those surfaces, reacted to by the interior forces of the earth, which the sun, as it were, governs, both by its direct action, gravitative, calorific, light-giving, and magnetic; and also indirectly, through that of the waters and the air upon the land, the solid, liquid, and aëriform elements of the crust being thus all subject to its action; while a certain amount of action is also exerted upon them by the radiation of the stars, the suns of other systems. On the surface of the earth, therefore, in its most comprehensive sense, are inscribed the indelible and enduring records of all the activities, terrestrial, solar, and celestial, which have produced, and are perpetually reproducing it; and on that of the terraqueous globe, thus maintained in equilibrium, organic nature and man exist, the well-being of the latter being the end, or final cause, of the whole.

SURFACES OF THE SECOND DEGREE. This name is given to all those surfaces of which the equation is of the second degree, or can be made a case of

$$\begin{gathered} ax^2+by^2+cz^2+2a'yz+2b'zx+2c'xy \\ +2a''x+2b''y+2c''z+f=0, \end{gathered}$$

to which form any equation of the second degree between three variables may be reduced. These surfaces hold the same place among surfaces which is held by curves of the second degree, or conic sections, among curves; and every section made by a plane with any surface of the second degree must be a curve of the second degree. The following article is intended entirely for reference, as the books which treat on the subject hardly ever give the complete tests for the separation of the different cases from each other.

1. The preceding equation may be wholly impossible, or incapable of being satisfied by any values of x, y, and z. This happens when the left-hand side can be resolved into the sum of any number of squares which cannot vanish simultaneously.

2. It may represent only one single point. In this case the left-hand side can be resolved into the sum of three squares, which vanish simultaneously for one set of values of x, y, and z.

3. The equation may belong to a single straight line. In this case the left-hand side can be resolved into the sum of two squares.

4. The two last cases have a particular case which is algebraically very distinguishable from the rest, though it can only be geometrically represented by saying that the point or line is at an infinite distance from the origin.

5. The equation may belong to a single plane. In this case the left-hand side is a perfect square.

6. Or to a pair of planes, either parallel or intersecting. The left-hand side can then be resolved into two different factors of the first degree.

In the preceding cases there is no other surface than can be represented by one or several equations of the first degree. We now come to the cases in which new surfaces, not plane, are generated. But we may first observe that the left-hand side of the equation has a property much resembling a celebrated one of integer numbers. If it be the sum of any number of squares exceeding four, it may be reduced to the sum of four squares at most.

7. The equation may belong to a cone, having for its base any one of the conic sections. But in every case the same cone may be described by a circle only: that is, every cone of the second order is a circular cone, right or oblique. In this case, the first side of the equation takes the form $P^2+Q^2-R^2$, or $P^2-Q^2-R^2$, P, Q, and R being expressions of the first degree, of the form $Ax+By+Cz+E$.

8. The equation may belong to a cylinder having for its base any conic section. But the elliptic, parabolic, and hyperbolic cylinders are perfectly distinct. In this case the first side of the equation can be reduced to the form P^2+mQ^2+nQ, P and Q being expressions of the first degree, and m and n constants.

9. The equation may belong to an *ellipsoid*, a *single hyperboloid*, a *double hyperboloid*, an *elliptic paraboloid*, or an *hyperbolic paraboloid*. These five are the distinct surfaces of the second degree, answering to the three distinct curves of the second degree—namely, the ellipsoid to the ellipse, the two hyperboloids to the hyperbola, and the two paraboloids to the parabola. They will presently be further described; in the mean time the forms to which the left-hand side of the equation may be reduced in these several cases are—

Ellipsoid $P^2+Q^2+R^2-m^2$.
Single Hyperboloid $P^2+Q^2-R^2-m^2$.
Double Hyperboloid $P^2-Q^2-R^2-m^2$.
Elliptic Paraboloid P^2+Q^2+mR.
Hyperbolic Paraboloid P^2-Q^2+mR.

The conditions under which the several cases are produced are exhibited in the following table. Let

$$V_1=a+b+c$$
$$V_2=bc+ca+ab-a'^2-b'^2-c'^2$$
$$V_3=abc+2a'b'c'-aa'^2-bb'^2-cc'^2$$
$$V_4=(bc-a'^2)\,a''^2+(ca-b'^2)\,b''^2+(ab-c'^2)\,c''^2$$
$$+2\,(b'c'-aa')\,b''c''+2\,(c'a'-bb')\,c''a''+2\,(a'b'-cc')\,a''b''$$

$$W=-\frac{V_4}{V_3}+f$$

When $V_3=0$, V_4 is a perfect square: if V_4 also $=0$, the three expressions

$$\frac{ba''^2-2c'a''b''+ab''^2}{ac-c'^2},\ \frac{ac''^2-2b'c''a''+ca''^2}{ca-b'^2},\ \frac{cb''^2-2a'b''c''+bc''^2}{bc-a'^2}$$

are all equal. Let either of them, with its sign changed, and increased by f, be called W'. Again, when any three of the six quantities

$$bc-a'^2,\quad ca-b'^2,\quad ab-c'^2$$
$$b'c'-aa',\quad c'a'-bb',\quad a'b'-cc'$$

vanish, the other three also vanish. Let these vanish, and also let a'', b'', c'' be in the proportion of a, c', b', or of c', b, a', or of b', a', c. When this happens, the three following

$$\frac{a''^2}{a},\quad \frac{b''^2}{b},\quad \frac{c''^2}{c}$$

are equal: let either, with its sign changed, and increased by f, be called W''. The table is then as follows, in which p means either of the signs + or −, and n means the other; and a supposition put in parentheses means that it is a necessary consequence of what precedes or is not independent.

W	V_3	W'	V_2	W''	V_1	Surface.
p	p		+		p	Impossible.
p	n		+		n	Ellipsoid.
p	p		+		n	Single Hyperboloid.
p	p		−			do. do.
p	n		+		p	Double Hyperboloid.
p	n		−			do. do.
∞	(0)		+			Elliptic Paraboloid.
∞	(0)		−			Hyperbolic Paraboloid.
0	p		+		p	Point.
0	p		+		n	Cone.
0	p		−			do.
$\frac{0}{0}$	(0)	p	+		p	Impossible.
		p	+		n	Elliptic Cylinder.
			−			Hyperbolic Cylinder.
		∞	(0)			Parabolic Cylinder.
		0	+			Straight Lines.
		0	−			Intersecting Planes.
		$\frac{0}{0}$	(0)	p	p	Impossible.
				p	n	Parallel Planes.
				0		Single Plane.
				∞		

For example, it is the condition of an ellipsoid that W and V_3 should be finite with different signs, that V_2 should be positive, and V_1 of the same sign as V_3: it is the condition of intersecting planes that W should have the form $0\div 0$, or that V_4 and V_3 should both vanish: that W' should also vanish; and that V_2 should be negative. It is the condition of a single hyperboloid, if V_2 be positive, that W and V_3 should both differ in sign from V_1; but if V_2 be negative, it is enough that W and V_3 should have the same sign. All that precedes is equally true whether the co-ordinates be oblique or rectangular; but the following is only true for rectangular co-ordinates: if the surface be a surface of revolution, it is necessary that

$$\frac{b'c'-aa'}{a'}=\frac{c'a'-bb'}{b'}=\frac{a'b'-cc'}{c'}.$$

The forms of the ellipsoid and of the two hyperboloids may best be conceived by means of the particular cases in which they are surfaces of revolution. Let an ellipse revolve about one of its axes, and let all the circular sections be flattened into ellipses: the result will be an ellipsoid, derived from its particular case, the spheroid. Let an hyperbola revolve about its minor axis; the two branches will generate only one branch of a surface: let the circular sections be flattened into ellipses, and the result is the single hyperboloid. Let the hyperbola revolve about its major axis: the two branches will generate two branches of a surface; and if the circular sections be flattened into ellipses, the result is the double hyperboloid. For the elliptic paraboloid, let a parabola revolve about its principal axis, and let the circular sections become ellipses. The hyperbolic paraboloid has no surface of revolution among its cases, but its form may be conceived as follows:—Let two parabolas have a common vertex, and let their planes be at right angles to one another, being turned contrary ways. Let the one parabola then move over the other, always continuing parallel to its first position, and having its vertex constantly on the other: its arc will then trace out an hyperbolic paraboloid.

The ellipsoid and the two hyperboloids have centres, but neither of the paraboloids has one. The surfaces which have centres possess an infinite number of triple systems of diameters having properties corresponding to those of the conjugate diameters of an ellipse and hyperbola. These we shall not describe, but shall proceed to point out how to determine the position of the centre and principal diameters or axes (that is, the system of conjugate diameters, each of which is at right angles to the other two) in either of the surfaces having a centre. Resuming the original equation, and the co-ordinates being supposed rectangular, the co-ordinates of the centre, X, Y, and Z, are thus determined. They are fractions whose denominator is $-V_3$, and whose numerators are

$$(bc-a'^2)a''+(a'b'-cc')b''+(c'a'-bb')c''$$
$$(ca-b'^2)b''+(b'c'-aa')c''+(a'b'+cc')a''$$
$$(ab-c'^2)c''+(c'a'-bb')a''+(b'c'-bb')b''\,;$$

and if the origin be removed to the centre, the axes retaining their original directions, the equation of the surface becomes

$$ax^2+by^2+cz^2+2a'yz+2b'zx+2c'xy+W=0,$$

where W is the expression already signified by that letter, and will be found to be also $Xa''+Yb''+Zc''+f$.

Let the three principal axes now make angles with the axes of x, y, and z, as follows:—The first, angles whose cosines are α, β, γ; the second, angles whose cosines are α', β', γ'; the third, angles whose cosines are α'', β'', γ''. The equation

$$r^3 - \mathrm{V}_1 r^2 + \mathrm{V}_2 r - \mathrm{V}_3 = 0$$

has always three real roots; let them be A, A', A''. Then the directions of the principal axes are to be determined from

$$\alpha^2 = \frac{bc - a'^2 - (b+c)\mathrm{A} + \mathrm{A}^2}{(\mathrm{A}-\mathrm{A}')\,(\mathrm{A}-\mathrm{A}'')}$$

$$\beta^2 = \frac{ca - b'^2 - (c+a)\mathrm{A} + \mathrm{A}^2}{(\mathrm{A}-\mathrm{A}')\,(\mathrm{A}-\mathrm{A}'')}$$

$$\gamma^2 = \frac{ab - c'^2 - (a+b)\mathrm{A} + \mathrm{A}^2}{(\mathrm{A}-\mathrm{A}')\,(\mathrm{A}-\mathrm{A}'')}.$$

To find α'^2, &c., interchange A and A' in the above; and to find α''^2, &c., interchange A and A''. The principal axes being thus determined, the equation to the surface, referred to the principal axes, is

$$\mathrm{A}x^2 + \mathrm{A}'y^2 + \mathrm{A}''z^2 + \mathrm{W} = 0,$$

a form which is fully considered in all elementary works on the subject, and from which the principal properties are derived. ('Algebraic Geometry,' in the Library of Useful Knowledge.)

For the proofs of the preceding assertions, and their extension to oblique co-ordinates, see a paper 'On the General Equation of Surfaces of the Second Degree,' in the 'Cambridge Philosophical Transactions,' vol. v., part 1. Under the form of considering the surface of the second degree, we have in fact been treating the general properties of the equation of the second degree, with three variables, and have solved various other problems of geometry and mechanics. The principles applied in this solution have been generalised in a paper on 'Linear Transformations,' by Mr. Boole. ('Cambr. Math. Journ.,' vol. iii., p. 1.)

SURGEONS, COLLEGE OF. The present College of Surgeons of England had its origin in the Company of Barber-Surgeons, which was incorporated by royal charter in the first year of Edward IV. By this charter of 1 Edward IV., the barbers practising surgery in London, who had before associated themselves in a company, were legally incorporated as the Company of the Barbers in London. Their authority extended to the right of examining all instruments and remedies employed, and of bringing actions against whoever practised illegally and ignorantly; and none were allowed to practise who had not been previously admitted and judged competent by the masters of the company.

This charter was several times confirmed by succeeding kings, but in spite of it many persons practised surgery independently of the company, and at length associated themselves as members of a separate body, and called themselves the surgeons of London. In the 3rd year of Henry VIII. it was enacted "that no person within the city of London, or within seven miles of the same, should take upon him to exercise or occupy as a physician or surgeon, except he be first examined, approved, and admitted by the bishop of London or by the dean of St. Paul's for the time being, calling to him four doctors of physic, and for surgery other expert persons in that faculty." All who under this act obtained licence to practise were of course equally qualified, whether members of the company of barbers or not; and in the 32nd year of Henry VIII. the members of the latter company, and those who had incorporated themselves as the company of surgeons, were united in one company, "by the name of masters or governors of the mystery and commonalty of barbers and surgeons of London."

In the 18th year of George II. an act was passed by which the union of the barbers and surgeons was dissolved, and the surgeons were constituted a separate company; and in the 40th year of George III. a charter was granted by which it was confirmed in all the privileges which had been conferred upon it by the act of George II. By this charter the title of the company was altered from that of the masters, governors, and commonalty of the Art and Science of Surgeons to that of the Royal College of Surgeons in London. Under this charter it was governed by a council or court of assistants, consisting of twenty-one members, of whom ten composed the court of examiners. Of these ten one was annually elected president, or principal master, and two were annually chosen vice-presidents or governors. By the bye-laws which the council were empowered by the charter to make, the members of the council were to be chosen for life from those members of the College whose practice was confined to surgery, and were to be elected by ballot at a meeting of the council. The examiners were generally chosen in order of seniority from the members of the council: the presidents and vice-presidents were chosen in rotation from the court of examiners, the president for the current year having been the senior vice-president during the past year.

A new charter was granted to the College of Surgeons in the 7th year of Victoria, by which it is declared, that the name of the college shall henceforth be The Royal College of Surgeons of England; and that a portion of the members of the said college shall be fellows thereof, by the name of The Fellows of the Royal College of Surgeons of England. The charter declares that the present president and two vice-presidents and all other the present members of the council of the said college, and also such other persons, not being less than 250 nor more than 300, and being members of the said college, as the council of the college, at any time before the expiration of three calendar months from the date of the charter, shall elect and declare to be fellows in manner by the charter directed; together with any such other persons as the council of the said college, after the expiration of the said three calendar months and within one year from the date of the charter, shall appoint in manner by the charter authorised, shall be fellows of the said college. But no person, except as hereinbefore named, is to become a fellow, unless he shall have attained the age of twenty-five years, and complied with such rules as the council of the college shall think fit, and by a bye-law or bye-laws direct; nor unless he shall have passed a special examination by the examiners of the said college. Every person admitted as a fellow, as last mentioned, is to become a member of the College by such admission, if he is not already a member. Henceforth, no member of the College, who is not a fellow, is to be eligible as a member of the council. There are also (10) some other restrictions as to eligibility. The present members of the council are to continue life members as heretofore; and the number of members of council is to be increased from twenty-one to twenty-four, and all future members are to be elective, and to be elected periodically, in the manner prescribed by the charter (12) when the number of elective members of the council shall be completed and made up to twenty-four. Three members shall go out annually, but they may be re-elected immediately. The members of council are to be elected by the fellows, including the members of the council as such, in the manner prescribed by the charter (15); and the election is to be by ballot (17). There are various special provisions as to the eligibility of fellows, for which we refer to the charter. There are to be ten examiners of surgeons for the college, and the present examiners are to continue for life; and all future examiners are to be elected by the council, either from the members of the council, or from the other fellows of the college, or from both of them; and all future examiners of the college shall hold their office during the pleasure of the council. The charter contains other regulations, and confirms the powers of the college and the council, except so far as they are altered by the charter; and it declares that no bye-law or ordinance hereafter to be made by the council shall be of any force until the crown shall have signified its approval thereof to the college under the hand of one of the principal secretaries of state, or otherwise as in the charter stated (22). "The Bye-Laws and Ordinances of the Royal College of Surgeons of England" contain the regulations as to the candidates for the fellowship (sect. 1), for the examination of candidates for the fellowship (2), admission of fellows (3), election of members of council (5). By section 1, it is required that every candidate for the fellowship, among other certificates, shall produce a certificate, satisfactory to the court of examiners, that he has attained a competent knowledge of the Greek, Latin, and French languages, and of the elements of mathematics. The subjects of examination for the fellowship are Anatomy and Physiology on the first day, and Pathology and Therapeutics and Surgery on the second day. The examination is to be by written answers to written or printed questions; but any candidate may be interrogated by the examiners, on any matter connected with the questions or answers. In the anatomical examination the candidate must also perform dissections and operations on the dead body in the presence of the examiners.

By a recent bye-law members are eligible to the fellowship by election. Any member of the College, of fifteen years' standing, who was a member on the 14th of September, 1843, desirous of admission to the fellowship otherwise than by examination, must sign a declaration of not selling or supplying drugs or medicines, which must be accompanied by a certificate recommending him to the fellowship, signed by six fellows of the college. The signing of the certificate is subject to some alterations for surgeons in the army and navy, and in the British colonies.

Persons are admitted to examination for the membership of the College on producing certificates of being twenty-one years of age; of having been engaged four years in the acquirement of professional knowledge, and of having attended lectures on anatomy, surgery, and other branches of professional knowledge for four years; of having dissected and attended hospital practice during three winter and two summer sessions.

The examination for the diploma of member is divided into two parts, the first relating to anatomy and physiology, the second relating to pathology, surgery, and surgical anatomy. The latter examination is partly written and partly oral. The examination on anatomy is on the recently dissected subject. Students who have completed their second session of anatomical studies are eligible for undergoing the first part of this examination.

The College also gives an especial certificate of qualification for the practice of midwifery. Members or fellows of the College previous to the 1st of January 1853, are eligible to this examination at once. Members or fellows admitted since 1853 have to produce a certificate of having attended at least twenty labours. Members of other Colleges of Surgeons, or graduates of universities, are also admitted to examination for this certificate. Persons not having any diploma, but producing evidence of having completed their professional education, and of having attended one course of lectures on midwifery, and of having personally attended thirty labours, are also admitted to examination for this certificate.

By the new medical act (21 & 22 Vict. c. 90, s. 48), it was enacted that it shall be lawful for her Majesty to grant to the Royal College of Surgeons power to institute and hold examinations for the purpose of testing the fitness of persons to practise as dentists, who may be desirous of being so examined, and to grant certificates of such fitness. The college has since granted a large number of certificates to persons practising as dentists alone.

The Licentiates of the Royal College of Surgeons in Ireland, of the Royal College of Surgeons of Edinburgh, and of the Faculty of Physicians and Surgeons of Glasgow are admissible to the membership of the College under the bye-laws relating to *ad eundem* admissions.

The museum of the College consists of the collection made by John Hunter, which was given in trust by government, who purchased it for 15,000*l.*, and of numerous additions made to it by donations of members and others, and by purchase. The parts of it which illustrate physiology, palæontology, and morbid anatomy are probably the most valuable collections of the kind in Europe. [HUNTER, JOHN, in BIOG. DIV.]

Lectures on anatomy, for which 510*l.* were left to the company of barber surgeons by Edward Arris, and 16*l.* per annum by John Gale, are delivered annually by one of the members of the council or some other member selected by them. Twenty-four museum lectures are also, in compliance with the deed of trust, annually delivered by the Hunterian professor, the subjects of which must be illustrated by preparations from the Hunterian collection, and from the other contents of the museum. An oration in commemoration of John Hunter, or of others who have been distinguished in medical science, is delivered annually on the 14th of February, the anniversary of Hunter's birth.

The College gives also three prizes for the best essays on anatomical and surgical subjects; one, "the Collegiate Triennial Anatomical Prize of fifty guineas;" the other two, "Jacksonian Prizes" of twenty guineas each, are given every year.

The library is very extensive, and is open to all students, members and fellows, from 10 till 4 o'clock.

Abstracts of the several acts and charters relating to the College of Surgeons may be found in Willcock, 'On the Laws relating to the Medical Profession,' London, 1830, 8vo, and in Paris and Fonblanque's 'Medical Jurisprudence,' vol. iii. The bye-laws, the list of members, the catalogues of the museum and library, &c., are published by the College.

SURINAMINE. An alkaloid of unknown composition found in the bark of a plant of the genus *Geoffræa* growing in Surinam and Jamaica.

SURNAME. [NAME.]

SURPLICE, the white dress worn by the clergy in their acts of ministration, from the Latin *superpelliceum*. It differs from the *albe* in having wider sleeves. It appears to have been introduced in order to make a distinction between the dresses which the superior and the inferior orders of the clergy wore at the Liturgy; and from about the 12th century the name of surplice was introduced. During the middle ages, bishops very frequently wore the surplice with a cope, and above the rochette. (Bona, *Rerum Litury.*, lib. i., cap. 24, s. 20; Palmer's *Orig. Liturgicæ*, vol. ii.)

SURRENDER. "*Sursum redditio* properly is a yielding up of an estate for life or years to him that hath an immediate estate in reversion or remainder, wherein the estate for life or years may drown by mutual agreement between them." A surrender and a release both have the effect of uniting the particular estate with that in reversion or remainder; but they differ in this, that whereas a release generally operates by the greater estate descending on the less, a surrender is the falling of the less estate into the greater.

Coke mentions three kinds of surrenders: 1. A surrender at common law, which is the surrender properly so called; 2. A surrender by custom of copyhold lands or customary estates; and, 3. A surrender improperly taken, as of a deed, a patent, of a rent newly created and of a fee-simple to the king.

1. The surrender at common law is of two sorts: 1. A surrender in deed or by words in writing, expressing the intention of the owner of the particular estate to yield it up to him in reversion or remainder; and, 2. A surrender in law, which is wrought by operation of law, and not actual; as if a lessee for life or years takes a new lease of the same land during the continuance of his term, this will be a surrender in law of the prior lease.

The surrender of terms of years will sometimes be presumed from length of time alone; and many cases have arisen upon the question, after what periods mortgage terms have been satisfied, and terms which have been assigned to trustees to attend the inheritance and have not been subsequently dealt with, will be presumed to have been surrendered.

2. As to surrender of copyholds, see COPYHOLD.

3. A surrender may be made of letters-patent and offices to the crown, to the intent that a fresh grant be may made of the same right; and a grant of the second patent for years to the same person, for the same thing, causes a surrender in law of the first.

SURROGATE, is, according to Cowell's 'Interpreter,' "one that is substituted or appointed in the room of another, most commonly of a bishop or a bishop's chancellor."

The qualifications required in a person appointed as surrogates are defined and enforced by the canons of 1603. He must be a grave minister and a graduate or a licensed preacher and beneficed, or a bachelor of law or a master of arts, well qualified from his religion and learning.

Surrogates being delegated officers, their jurisdiction of course depends upon that of the person for whom they act. The principal duty however of ecclesiastical surrogates may be stated to consist of taking affidavits in the ecclesiastical courts and granting marriage licences. The proper performance of these duties is guarded by particular enactments. By the 26 Geo. II. c. 33, § 7, every surrogate deputed by any ecclesiastical judge who has power to grant licences of marriage is required, before granting any such licence, to take an oath before such judge and to give a bond of 100*l.* to the bishop of the diocese for the faithful execution of his office.

Surrogates are also persons appointed to execute the offices of judges in the courts of Vice-Admiralty in the colonies, in the place of the regular judges of those courts. The acts of such surrogates have, by the 56 Geo. III., c. 82, the same effect and character as the acts of the regular judges.

SURVEYING is the art of determining the form and dimensions of tracts of ground, the plans of towns and single houses, the courses of roads and rivers, with the boundaries of estates, fields, &c. A survey is accompanied by a representation on paper of all the above-mentioned objects, and frequently by a delineation of the slopes of the hills, as the whole would appear if projected on a horizontal plane. When canals or railways are to be executed, a survey of the ground is combined with the operations of levelling, in order to obtain, besides a horizontal plan, the forms of vertical sections of the ground along the proposed lines, and thus to ascertain the quantities of earth to be removed.

In maritime surveying, the forms of coasts and harbours, the entrances of rivers, with the positions of islands, rocks, and shoals, are to be determined; also the soundings or depths of water in as many different places as possible.

Military surveying consists chiefly in representing on paper the features of a country, such as the roads, rivers, hills, and marshes, in order to ascertain the positions which may be occupied as fields of battle or as quarters; and the facilities which the country may afford for the march of troops or the passage of artillery stores.

For trigonometrical surveying, see TRIGONOMETRY.

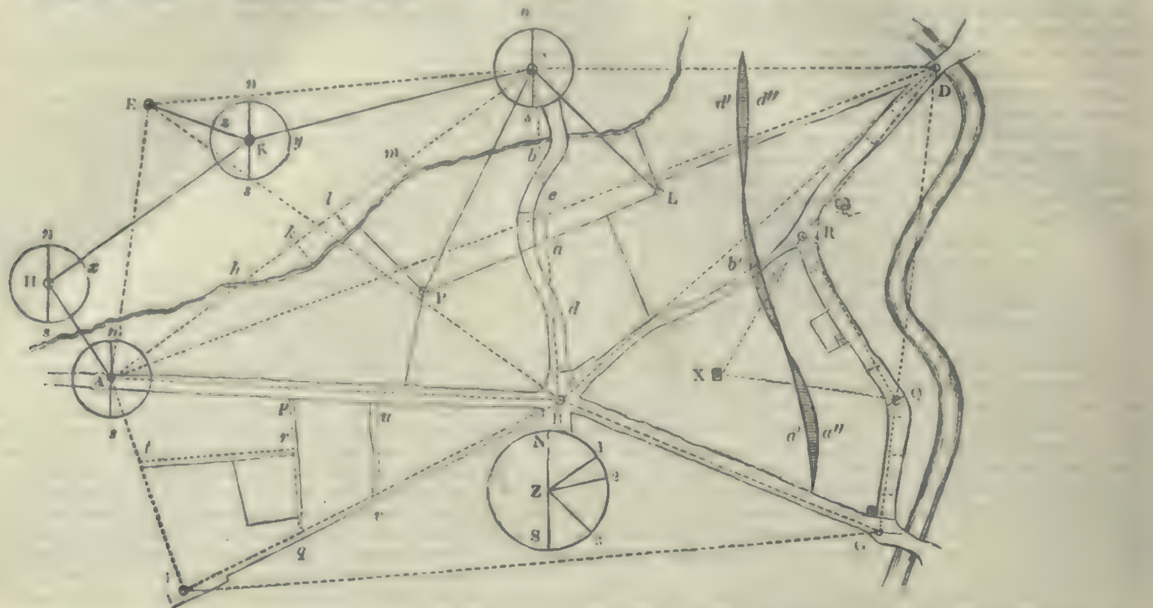
Since the measurement of the distance between two objects by means of a rod or chain is very laborious and inaccurate when that distance is considerable, particularly if the ground should have many inequalities of level, and be much intersected by walls, hedges, and streams of water, it will seldom be possible to execute even an ordinary survey by such means alone, and instruments for taking angles must be employed, together with the chain, in every operation of importance.

If within the tract to be surveyed there should be a road about half a mile in extent, and nearly straight and level, so that a line may be accurately measured upon it by the chain, and that from its extremities several remarkable objects, as churches or mills, may be seen, it will be convenient to use such measured line as a base, and with a theodolite to observe the angles contained between the base and the lines joining the extremities to the different objects. The three angles of each triangle formed by such lines should if possible be observed, in order that by the agreement of their sum with 180° the accuracy of the angular measurements may be tested; and then the lengths of the sides of the triangles may be determined by the rules of plane trigonometry.

Let A B represent a base so measured in a road; and let C, D, E, F be four remarkable objects within or near the boundaries of the tract to be surveyed; the distances A C, A D, &c., B D, B C, &c., will be those which should be determined by computation. These lines may then serve as bases, and if from their extremities be taken the angles contained between them and lines supposed to connect them with any other objects, as houses or remarkable trees, the positions and distances of these objects may be determined by computation as before. Thus B C or B D will serve as a base by which the position of G may be computed.

It will obviously be advantageous if the lines supposed to connect the objects lie nearly parallel to the directions of roads, lanes, streams, or hedges, on account of the facility which will thereby be afforded for laying down such roads, &c., on the plan. In order that it may be possible to place the theodolite at the angular points of the triangles, those points should not be precisely in the churches, mills, or other objects whose positions are to be determined, but should be indicated by poles set up near those objects, on spots of ground in such situations that each may be visible from the two others which with it constitute the intended triangle. The place of the building may be ascertained by its bearing and distance from the pole in its vicinity. After as many stations as may be thought fit have been determined in the manner just described, and the lengths of the lines (that is, the sides of the triangles) connecting them have been computed, the survey may be completed by actual admeasurements with the chain, in each triangle separately.

Poles having been set up at the angular points of every triangle, the surveyor and his assistant set out from any one of these points, as B, and proceeding across the ground, measure the whole length of any one line, as B C, leaving pickets in the ground in the direction of the line at or near every place where it crosses a hedge, as at *a*, a stream, as at *b*, a road, or any other object which is to be introduced in the plan. Should it happen that the line B C, or any part of it, coincide with the direction of a road, offsets, as they are called, are measured perpendicularly to the line, on one or both sides of it, in order to express the distance from the line to the sides of the road, or to the hedges or walls along those sides; these offsets (which are shown at *c*, *d*, and *e*) should be measured at the end of every chain's length, and particularly at every point in the station line opposite to which there is a remarkable object, as a house, a gate, or merely a bend in the direction of the road. Thus, when the work is laid down on paper, the precise form and breadth of the road will be expressed.



In like manner the other side, A C, of the triangle, is to be measured with the chain; pickets are to be left in the ground at or near every place where a stream, as at *h*, a road, or a hedge crosses the side of the triangle; and offsets, as at *k*, *l*, *m*, are to be measured from the station line to and across such boundaries as may be nearly parallel to any part of its direction. The like process is to be followed on each side of every triangle; the measured lengths of the sides of each triangle should then be compared with the computed lengths; and if the difference be not considerable, the work may be considered as having been performed with sufficient accuracy; otherwise the operations must be repeated, in order that the source of the error may be detected.

To carry on the work in the interior of any angle, as A B F, the surveyor, where it is possible, measures with the chain the direct distance from the pickets in one side of the triangle to the pickets in another side, as *nv*, *pq*; and since these pickets are supposed to have been placed near the intersections of boundary-lines (roads, streams, or hedges) with the sides of the triangle, the lines last measured will, at least in part of their length, coincide with or be parallel to some of the boundaries in the interior of the triangle; and the precise figures of such boundaries will be determined as before by offsets from the measured line to all the principal bends. The length of each of these secondary station lines may be obtained by trigonometry, since the line is the base of a secondary triangle of which the two sides are known, being measured parts of two sides of the principal triangle, and the angle included between those sides has been found by the theodolite; therefore the measured length of this line, on being compared with the computed length, will afford an additional test of the accuracy of the work.

In measuring these secondary lines within each principal triangle, pickets must, as before, be left in the ground in the direction of the line, at or near places, as at *r*, where hedges, walls, &c., cross the line; and from one of these pickets, *r*, to another, as *t*, lines are afterwards to be measured (these being as much as possible in or near the direction of other boundaries), till at length the whole interior of each principal triangle will have been divided into several secondary triangles, all the sides of which have been measured. These sides, by means of the offsets which have been measured from them, determine the figures of all the natural and artificial boundaries within the tract of ground.

The situations of the buildings are also determined by offsets from the station lines nearest to them: the ground plans of the more considerable edifices, as churches and mansions, are measured, and the directions of their fronts with respect to the meridian are ascertained by a compass or otherwise.

When rivers or roads have many abrupt and deep bends, the determination of their forms by means of offsets from the station-lines may become impracticable; and then a separate survey of such details must be made by means of the compass, the circumferentor, or the theodolite. [THEODOLITE.] The same means must be employed for the survey of a sea-coast, when the operation is to be performed on land; and it may often be advantageous to determine in like manner the forms of the hedges, walls, &c., in the interior of the tract which is to be surveyed. Ground covered with wood must be surveyed by going quite round it; poles being set up at remarkable bends on the contour, the distances between them are measured with the chain, and the bearings of the several lines from the meridian are observed with the theodolite.

In order to explain the process of surveying with the theodolite by the method which is commonly called that of the "back-angle," and which is now almost constantly adopted, let it be required to determine the outline H K C L B A, which may represent the contour of a wood, or of which part may coincide with the course of a road or river. The instrument may be set up at H, which may be supposed to be the first station; and let the line *n s* at each of the stations H, K, C, &c., represent the position of the needle or of the magnetic meridian at the station: also let the instrument be adjusted so that the zero point of the horizontal limb may be under the point *n* (the north point of the needle), or the zero of the degrees in the compass-box may be in coincidence with *n*; and let K be the second station. Turn the upper horizontal plate with the telescope till the object-glass of the latter is directed to K, and make the intersection of the wires appear to coincide with the object at that station; then the index of the vernier will be at some graduation on the lower horizontal plate, as at *x*, and the angle *n* H K is that which is observed; suppose it to be 54°, reckoning from the north towards the east, which angle is usually represented by N. 54° E. [N.B. Previously to directing the object-glass to K, it might have been directed to any other visible objects, as F or D, whose positions it might be required to determine by means of their bearings from the meridian line.]

Let the theodolite be now removed to K, a staff being planted in the ground at H: turn the whole instrument round on its vertical axis (the index of the vernier remaining at the graduation N. 54° E.) till the object-glass of the telescope is directed to H, and the intersection of the wires appears to coincide with the staff there. Then, if the former angle were correctly taken, and no movement of the horizontal plates on one another have taken place, the south point *s* of the needle will lie over the zero of the graduations on the lower plate, or will coincide with the zero of the degrees in the compass-box; and this circumstance will be a proof of the accuracy of the work, all the meridian lines *n s*, *n s*, being supposed to be parallel to one another.

Now turn the upper horizontal plate with the telescope, till the object-glass of the latter is directed to C, and the intersection of the wires appears to coincide with the object there: the telescope in moving from the position K H to the position K C having passed over and beyond *s*; and the index of the vernier being supposed to be at *y*, the number of the graduation, these being read from *s* in the direction *sny*, will be greater than 180: let it be 256 (or 180° + 76°): in that case the observed angle is N. 76° E., and it expresses the bearing of the line K C from the meridian *n* K *s*, or from the meridian *n* H *s*. If the telescope in moving from K H should be directed to an object at E, then, the index of the vernier being supposed to be at *z*, the number of the graduation will be less than 180°: let it be 110 (or 180°—70°); in that case the observed angle is N. 70° W., and it expresses the bearing of the line K E from the meridian *n* K *s* or *n* H *s*.

Let the theodolite be removed to C, a staff being left at K, and turn the whole instrument, the index of the vernier remaining at N. 76° E., till the object-glass of the telescope is directed to K, and the intersection of the wires appears to coincide with the staff there; then the point *n* of the needle should lie over the zero of the graduations. Now turn the upper horizontal plate till the object-glass of the telescope is directed to L, and the intersection of the wires appears to coincide with the object there; then the telescope, in turning from the position C K to C L, passing over and beyond *s*, the number of the graduation coincident with the index of the vernier will (reckoning from zero at *n*) be less than 180; let it be 133°: in that case the observed angle is N. 133° E., or S. 47° E., and it expresses the bearing of the line C L from the meridian *n* C *s* or *n* H *s*. If the telescope should not pass beyond *s*, and should be in the position C P, for example, the number of the graduation, reckoned from *n*, will be greater than 180; let it be 206, or 180° + 26°: in that case the observed angle is S. 26° W., or N. 206° E., or N. 154° W., and it expresses the bearing of the line C P from *n* C *s* or *n* H *s*. In this manner the process of the survey is continued to the end of the road, or till, having passed completely round the wood, the instrument returns to H, from whence it set out.

As, from local attractions or other causes, the polarity of the needle may not be constant, it is scarcely to be expected that the needle should, when the telescope is directed back to a preceding station, be exactly coincident with the north and south line in the compass-box: yet a near approach to such coincidence will serve to detect the existence of considerable errors in the observed angles; and a complete verification of the whole series of operations will be obtained, should the observed bearing of H from the meridian line *n* A *s* at the last station A, that is, the angle *n* A H, be found to agree with the observed bearing of A from the meridian line *n* H *s* at the first station H. When this agreement takes place the work is said to close accurately.

The survey of a road or an enclosure, by following the course of the former, or the contour of the latter, may be performed by simply observing with a surveying-compass or a circumferentor the bearings of the several station-lines from the magnetic meridian, and measuring their lengths; and one of these instruments is generally employed when great accuracy is not required.

The plane table, which is also occasionally employed for surveying ground, is a square board fitted upon a tripod-stand and furnished with compass, and with an *alidade*, or ruler carrying "sights" at the extremities. Drawing-paper is made fast to the board or table, and the instrument being set up at any part of the ground which may be thought convenient, a point is marked on the paper to represent the place. The alidade is next turned about that point, so that the line of the sights may be directed to any remarkable objects whose situations are to be determined, and lines are drawn by the edge of the ruler in its several positions: then the distance from the instrument to some one of those objects being measured, and laid down on its line of direction by a convenient scale, the place of that object on the paper is obtained. The table is then removed to that object, and fixed by the needle in the compass-box, so that its edges may be parallel to their former positions; that is, till the alidade placed on the line joining the places of the two objects of the paper is in a direction tending to the former place of the instrument. In this position, the alidade being turned about the point which represents the actual place of the instrument on the ground, lines are drawn as before along the edge of the ruler, towards the several objects which had been observed at the preceding station; the intersections of these lines with the others will determine the places of the objects on the paper.

The length of every line which is to be measured must be obtained in a direction parallel to the horizon between its extremities; and the determination of this length is generally a work of considerable difficulty on account of the inequalities of the ground.

Where great precision is required, it would be proper that the direction of the line to be measured should be indicated by pickets previously planted at intervals along it; a cord may be stretched tight between the two first pickets, and the measurement may be performed by means of a graduated deal-rod 15 or 20 feet in length, which should be applied successively to the cord, the place of each extremity of the rod being marked by a pin pressed into the cord. But when the ground is nearly level, a measuring-chain is laid upon the ground itself in the direction of the line to be measured, the leading man pressing into the ground, at the end of each chain's length, an iron pin, which being taken up by the person who follows, the number of pins so taken up serves to show the number of chains in the length of the line measured. In ascending or descending any gentle elevation of the ground, the chain should be held up at the lower end till it is in a horizontal position, as nearly as the chain-holder can estimate it; and a plummet being suspended from that extremity, so as to touch the ground vertically under it, the measurement thus obtained is in general sufficiently near the required horizontal length of the line. When the slope of the ground is too great to admit of this simple method being put in practice, the chain must be stretched on the ground, and then the angle at which it is inclined to the horizon being found by some instrument (a small spirit-level furnished with a graduated arc), the horizontal value of the chain's length must be computed. And if, at the same time, the vertical height of one end of the chain above the other be also computed, there will be afforded sufficient data for determining on paper the form of a vertical section of the ground in the direction of the measured line.

Where the rise or fall of the ground is considerable, the operation will be most conveniently and accurately performed by the use of a theodolite; for this purpose pickets should be set up in the ground, in the direction of the line to be measured, at every place where a change occurs in the inclination of the ground to the horizon, and marks made on them at heights above the ground equal to that of the telescope belonging to the theodolite; then, while the chainmen are employed in measuring the length of the line on the ground, the surveyor takes the angular elevations or depressions of the marks on the pickets, with respect to the horizon. From the data thus obtained the horizontal distances between points of ground, and the positions of the points above or below any assumed horizontal plane, can be computed. In order to save the trouble of making trigonometrical computations, the vertical arch of the theodolite usually carries two series of graduations, from which, by inspection, when the telescope is directed to an object, the portion of the measured line which should be subtracted from it in order to reduce it to the corresponding horizontal length may be found; and also the portion of that horizontal length to which the vertical height or depression is equal.

This method may be conveniently put in practice when it is required to exhibit sections of the ground, for the purpose of guiding the civil engineer in the choice of a line for a road or canal; the great accuracy with which the section might be determined by a spirit-level not being requisite. It is now the practice to represent on a plan of the ground a vertical section in the direction of a proposed line of road, for the purpose of showing the depths to which the excavations are to be carried, and the heights to which the embankments are to be raised; a strong line, as a', b', d', representing the surface of the proposed road: on one side of this line, as at a'', d'', are shown the profiles of the requisite excavation; and on the other side, as at b'', are shown the profiles of the embankments: both the heights and depths being determined with relation to the surface of the road. This method was first proposed by Mr. Macneil.

The principal and secondary station-lines constitute a triangulation on the plan of the ground; and when the lengths of these lines have been ascertained by admeasurement, the superficies of the whole track may be found by the rules of mensuration. The area of each triangle should be calculated separately from the measured lengths of the lines, and the several results added together, if all the triangles lie within the given boundaries of the tract; should any of them lie on the exterior of the boundary, the areas must of course be subtracted. But as the boundaries of the several fields, &c., seldom coincide exactly with the station-lines, offsets must have been measured from every such line to each remarkable bend in the nearest boundary; and between the station-line, the boundary, and every two offsets from the former, there exists a small trapezoid, whose area must be computed separately, and either subtracted from or added to the areas of the triangles formed by the measured station-lines, according as it lies within or on the exterior of these triangles.

The accurate method just described is not always put in practice by surveyors. When the boundaries of a field or tract of ground have numerous small bends, a straight line is sometimes drawn through portions of the boundary in such a manner that the small areas on the exterior of the line shall be equal to those which fall in the interior, this equality being estimated by the eye: the complex figure of the contour line is thus reduced to one more simple; and the area of the field or tract is then computed. For this purpose either the plan is divided into two or more triangles, or by a geometrical construction the whole irregular figure is reduced to one triangle of equal magnitude, and in either case the lengths of the sides are measured by the scale of the plan.

When a road, river, or any boundary-line is surveyed with the theodolite and chain, the successive operations are registered in a book according to a particular form, by which a person without any knowledge of the ground may be enabled with facility to lay the work down on paper. This is called the 'Field-Book,' and the manner of entering in it the series of operations will be best explained by means of an example. Let G, Q, R, D, be the principal bends in the direction of a road, and the stations at which, in succession, the theodolite is placed for the purpose of observing the bearings of the several lines G Q, Q R, and R D, from the magnetic meridian passing through the first station G.

At G let the bearing of the object, or mark set up at Q, be observed; let the line G Q be measured with the chain, and let offsets be measured perpendicularly to that line up to any remarkable points near it. At Q let the bearing of a staff at R be observed; also let the length of

Q R, and of several offsets from it at remarkable points towards the right and left hand along that part of the road, be measured. Again at R let the bearing of the staff at D be observed; let also the length of R D, and of various offsets along that line, be measured; and let it be supposed that the like process is continued as far as may be required.

Each page of the field-book is then divided, as below, into three columns by two parallel lines drawn down the page: and beginning at the bottom of the column, the several bearings of objects, the lengths of the station-lines, and the several offsets from those lines are inserted, in order, ascending towards the top of the page, the offsets being placed on the right or left hand of the middle column, conformably to their positions with respect to the station-line to which they belong. And it is on this account that the several entries are made in succession from the bottom upwards. The distances in the middle column between the stations G and Q are reckoned from G; those between Q and R are reckoned from Q, and so on, each number in that column expressing the distance up to the place in the station-line where the offset whose length is given immediately on the right or left hand of the number was taken. When it is required to determine by observed bearings the position of any object, as X, at a distance from the road, those bearings are also inserted in the field-book at the stations, as Q and R, where they were observed, and immediately under the bearing of the next forward station. The mark ⊙ is usually put to signify the word "station."

The term "plotting" is applied to the process of laying down on paper the plan of the ground which has been surveyed. If the survey has been performed by the chain only, the several station-lines constitute the sides of triangles extending over the whole of the ground; the lengths of those sides are determined by admeasurement, and in places where they do not coincide with the roads, hedges, &c., offsets are measured from the sides to the principal bends in those boundaries. In order to "plot" the survey in this case, a proper scale of graduations, usually representing "chains" and "links," is chosen, and the length of one of the station-lines taken from the scale being laid down on the paper as a base, from the two extremities of it as centres, with distances (taken from the scale) equal to the measured lengths of the two sides, which with the base form the first triangle, arcs are described to intersect one another; this intersection being joined to the extremities of the base by lines, the first triangle is constructed. Each side of this triangle is then used as a base on which another triangle is constructed with lines taken from the scale equal to the measured lengths of the sides, and so on. After the triangulation is thus formed, the offsets are laid down from them. This part of the process is accomplished by setting out with compasses upon each station-line, from one of its extremities, the several distances (taken from the scale) of the points at which the offsets were measured, drawing lines perpendicularly to the station-line at these points, and on them placing, from the scale, the measured lengths of the offsets: lines joining the extremities of these offset lines, either drawn by hand or with a ruler, will represent the lines of roads, the boundaries of fields, and the like. In order to facilitate the operation of laying down the offsets from the station-lines, the surveyor is usually provided with ivory scales graduated to represent chains and links on the edges; by laying an edge of such scale along the station-line, with the zero of the graduations at one end, the several distances of the offset-lines from that extremity can be marked on the line in succession; the scale may then be applied to each offset-line, and the measured extent marked by means of the graduations.

But plotting scales are frequently made with graduations along the edges, and with a short scale, also graduated on an edge, which is disposed at right angles to the length of the principal scale, and is capable of being moved to any part of that scale by having one of its extremities cut so as to slide in a groove formed in the direction of the length of the scale. The perpendicular scale is moved along the principal scale to the graduation which denotes the place of the offset, and the length of the latter is then marked by the graduations on the perpendicular scale. Since the offsets frequently occur on both sides of the station-line, the zero of the graduations on the perpendicular scale may be at some distance from the edge of the principal scale, which is then placed, not in coincidence with the station-line, but parallel to it at such a distance that the zero may always be in that line. By this contrivance, which was first proposed by Major Robe, the offsets from the line may be marked, whether they be above or below it, without displacing the principal scale. To find a convenient scale for plotting a survey, the length and breadth of the whole may be computed approximatively in order to ascertain the number of chains in such length or breadth, and then the dimensions of the paper in inches being known, the number of chains in each inch may be formed by proportion. Plans of estates are usually made from scales of 2, 3, or 4 chains in an inch, and the linear dimensions, on a plan made from a scale of 3 chains in an inch, are equal to $\frac{1}{2376}$ of the actual dimensions on the ground.

In important surveys, where the process consists in measuring a base-line, and observing with a theodolite the three angles of every triangle, the base is laid down on the paper from some scale as before; and at each of its extremities all the angles contained between the base-line and visual rays from different objects to that extremity are set out by means of a protractor. The intersections of the several lines from the opposite extremities of the base determine the positions of the objects, and form with the base the first triangles. The sides of these triangles become then the bases of other triangles, and the angles observed at the extremities of their sides must be set out by the protractor. If any of these lines should have been measured by the chain on the ground, the construction of the triangles by means of the angles may be verified by measuring the lengths of such lines on the scale by which the base-line was laid down. Offsets may also be laid down as already described.

But the practice in ordinary surveys is to observe by the "back angle," as before described, the bearings which the different station-lines make with the meridian-line passing through one of the stations, and to measure with the chain the length of each station-line. These bearings and lengths, together with the offsets, are registered in the field-book, and they are generally transferred to the paper in the following manner:—

A line, as N S, is drawn in any convenient part of the paper, generally in a direction parallel to the right and left sides, to represent the magnetic meridian; and any point Z is chosen in it, at which the centre of the protractor is placed. Then the bearings, or angles made with the magnetic meridian by the different station-lines, H K, K C, C L, &c., are set out by the graduations of the protractor about the point so chosen, and lines, as Z 1, Z 2, Z 3, &c., are drawn from this point through the mark made on the paper on setting out each angle. These lines are so numbered in order to indicate the particular station at which each angle was observed. Then if the assumed point Z on the meridian-line should be the place of the first station, the first line so drawn is in the direction of the first station-line; but if the assumed point is not the first station, the place of this first station must be chosen on the paper, as at H; and a line drawn through it, parallel to Z 1, will be the direction of the first station-line. Its extremity K, found by setting out its length from the plotting scale, will be the place of the second station. Through K a line is to be drawn parallel to Z 2, and this will be the direction of the second station-line, whose length K C must then be set out as before. This process is to be continued till all the station-lines have been laid down; when, if the survey should have been carried round the boundaries of a tract of ground, the second extremity of the last station-line will, provided the operations have been accurately performed, coincide with H, the place of the first station. From these lines the offsets must be set out as before described.

In order to set out the allotments of land in countries which, like some parts of North America, are covered with wood, the surveyor determines on the ground the position of a boundary-line comprehending an area of a square form, each side of which is six or eight miles in length. One of these spaces, which constitutes a township, is usually divided into squares of one mile on each side; and again, these are divided into squares of half or a quarter of a mile on each side.

The boundary-line of the township is determined by measuring with a chain a base-line six or eight miles in length, generally along one side of a square already marked out for some previous township; and at each extremity of this line carrying out one of equal length perpendicularly to the base. A line joining the farthest extremities of the last lines completes the square. In order to mark out the two sides which are perpendicular to the measured base, a circumferentor, or a large surveying-compass, furnished with plain "sights," and mounted on a stand, is used. The bearing of the intended line from the magnetic meridian being ascertained from the position of the base, and the instrument being set up at one extremity of that line, the line of the sights is turned so as to make with the needle of the compass an angle equal to that bearing; then the surveyor, looking in the direction of the sights, observes some remarkable tree, and causes the distance from his station to that tree to be measured, small trees, if such there be between himself and the object, being cut down. Notches are cut in the tree in order that it may be distinguished from the others, and the instrument is removed to the opposite side of the tree. The line of the sights is then turned so as to make the given angle with the needle, and the distance of the station to the next remarkable tree in the line is measured as before. This process is continued to the extremity of the line which is to be set out, and strong stakes are planted at the end of each mile, half mile, and quarter mile on the line. From these stakes the lines of division and subdivision are carried out in a similar manner.

When the allotments are contiguous to a road, or the bank of a river, a narrow front is measured along the road or river, and the boundary-lines are carried out, perpendicularly to the front, as far as may be requisite in order to comprehend between them the intended area.

SURVIVORSHIP. A question of life contingencies is said to be one of survivorship when a benefit depends upon the order of the deaths of individuals in such manner that it shall be necessary to calculate the chance of one individual dying before another in every year of life. This distinctive name depends therefore entirely upon the mathematical character of the problem, and of two questions, which both seem to depend on survivorship in the common sense of the word, one may really do so, in the technical sense, and not the other. Thus the question of finding the premium of an assurance on the death of A, provided B die first, is one of survivorship: but that of finding the value of an annuity on the life of A, to begin at the death of B, is not.

The *chance of survivorship* is that of one individual, now of a given age, surviving another, also now of a given age. The following table exhibits the chance of the older life surviving the younger, according to the Carlisle Table. Thus the chance that 65 shall survive 25 is ·110; consequently the chance of 25 surviving 65 is 1 − ·110 or ·890; and it is 890 to 110, or about 8 to 1, that of two persons aged 65 and 25, the elder shall die first.

SURVIVORSHIP. [JOINT TENANCY.]

SUSPENSION is a term used in law when a seignory, rent or other profit out of land, by reason of the unity of possession of the seignory, rent, &c., and of the land out of which they issue, are not *in esse* for a time, but may be revived or awaked. It differs from extinguishment, which is when the rent, &c., is gone for ever by reason of the estate in the land being coextensive with that in the rent, &c. (Co. Litt., 313, *a*.)

SUSPENSION BRIDGE. [BRIDGE, col. 354, &c.]

SUSPENSION, CENTRE OF. [CENTRE, col. 734.]

SUSPENSION, ECCLESIASTICAL, is a mode of censure or secondary punishment inflicted by the church on persons guilty of those minor offences which do not deserve the severer penalties of deprivation or excommunication. "In the laws of the church," says Bishop Gibson, "we read of two sorts of suspension—one relating solely to the clergy, the other extending also to the laity."

"That which relates solely to the clergy is suspension *ab officio et beneficio* (that is, the duties and income of his office) jointly, or *ab officio* or *beneficio* singly, and may be called a temporary degradation or deprivation, or both." "The other, which relates to the laity also, is suspension, *ab ingressu ecclesiæ* (that is, from entering the church), or from the hearing of divine service and receiving the holy sacrament, which may therefore be called a *temporary excommunication*." He also observes that the two sorts of suspension agree in this, that both are inflicted for crimes of an *inferior* nature; that both, in *practice* at least, are temporary; and lastly, both, if unduly performed, are attended with further penalties. (See Gibs., 'Cod.,' tit. xlvi., cap. 3.)

In the Roman Catholic Church various kinds of suspension were inflicted for a great variety of offences. A few may be mentioned to illustrate the nature of this punishment. A bishop might be suspended from wearing the sacred vestments of his order, or from exercising his power of collating, instituting, or presenting to livings, or from the exercise of his jurisdiction, or from his office and benefice, or even from entering the church. These various species of punishment were inflicted for such offences as delaying to consecrate a church after proper application, not punishing concubinary priests, or corrupt and irregular practices in instituting persons to ecclesiastical preferments. The inferior orders of the clergy and other religious persons might be suspended from their office or benefice, or from performing service, or from receiving the sacrament, or from entering the church. The offences so punished were delay or irregularity in the performance of their duties, not wearing a proper dress, violating the rules of their order with respect to eating and drinking, neglecting to receive the sacrament at Easter, or extortion.

Suspension was either imposed by sentence after trial, in which case it must have been preceded by admonition, or was ipso facto upon the perpetration of certain crimes. (Gibs., 'Cod.,' *ubi supra*.)

Suspension has been retained as a mode of punishment in the English church. By the 33rd canon of 1603, a bishop ordaining a person who has not a proper title, and refusing to maintain him till he prefer him to some ecclesiastical living, is to be suspended from giving orders during one year: by the 35th canon, a bishop admitting to sacred orders any one not properly qualified is to be suspended from making either deacons or priests during two years; and by the 36th canon, a bishop ordaining any one who has not subscribed in the manner required by that canon is to be suspended from giving orders during twelve months.

It is also declared by the 68th canon that a minister refusing to christen or to bury shall, except under circumstances particularly specified by the canon, be suspended by the bishop of his diocese from his ministry by the space of three months.

The above are the principal cases in which suspension still exists as a form of punishment in the church of England. With respect to the laity, this censure is now entirely disused.

SUTTEE (*Sati*, from the Sanskrit *sat*, good) properly means a chaste and virtuous wife, and in ordinary use is applied to one who burns herself on her husband's funeral pile. The term has been employed by Europeans to denote the act of self-immolation as practised by Hindu widows. When this practice was first introduced cannot be determined with any degree of certainty: it is described by the Greek writers of the age of Alexander, and by Mohammedan and Christian travellers of the 16th and 17th centuries. Diodorus (xix. 33) gives an instance of a suttee which occurred in the army of Eumenes upwards of 300 years before the Christian era; and he ascribes the zeal for this kind of self-sacrifice, in most instances, to the infamy which attached to those widows who refused to conform to the custom. This is also the view taken by our missionaries; but as Elphinstone ('History of India,' i.) justly observes, if the motive were one of so general an influence, the practice would scarcely be so rare. It is not improbable that the doctrine of transmigration generally held throughout India may have had some influence in the establishment of the custom of the suttee. A widow, by burning herself with the corpse of her husband, was to be immediately released from further migration, and enter at once on the enjoyments of Heaven, to which by this act she would also entitle the deceased. Again, perhaps the hope of meeting the departed in the Swarga (Sahagamana) would be sufficient to induce a faithful wife to sacrifice herself. But, however ancient, there are in fact no authentic ancient writings of India, whether legal or religious, which make any mention of it. It is certain that Manu, in his directions to Hindu widows (book v.), does not even allude to it. It cannot be denied, however, that some good Indian authorities recommend the practice, but by no means command it. According to a summary of the law and custom of Hindu castes, compiled by Arthur Steele, and printed at Bombay by order of the governor in 1827, the most virtuous mode of becoming a suttee is to die of affliction and grief on the husband's death. The usual practice, indeed, is self-immolation on the husband's funeral pile; but the many cases under which a widow is excused becoming a suttee, strongly support the supposition that none of the Hindu law-books imperatively command it. The success which has attended the attempts of the British government to abolish the suttee, is a sufficient proof that the natives themselves were not so averse to its suppression as had been expected. In 1826 the government declared the burning of a widow without the body of the deceased (*anumarana*), and under various other specified circumstances, illegal; and all persons, whether relations or others, aiding or abetting in such an act, either before or after the death of the husband, were to be committed for trial at the circuit courts, and were made liable to the punishments for murder and homicide. It was, however, not until 1829 that a regulation was passed, on the 14th December, by the governor-general, Lord W. Bentinck, in council, declaring the practice of suttee, or of burning or burying alive the widows of Hindus, with or without the body of the deceased (*anumarana* or *sahamarana*), to be illegal and punishable by the criminal courts. The practice is still retained in some of the independent governments of India, but is much less prevalent since its abolition in the English territories.

The mode of burning was the same throughout India, varying only according to the rank of the deceased or the province where it was performed. The accounts of all Eastern travellers abound with instances of suttees: it will be sufficient here to give a short sketch of the ceremony. The husband is directed by the physician, when there are no hopes of his recovery, to be carried to the river side, and the wife then breaks a small branch from the mango-tree, takes it with her, and proceeds to the body, where she sits down. The barber paints the sides of her feet red, after which she bathes, and puts on new clothes. During these preparations the drum beats a certain sound, by which it is known that a widow is about to be burnt with the corpse of her husband. On hearing this, all the village assembles. The son, or, if there be no son, a relation, or the head man of the village, provides the articles necessary for the ceremony. A hole is dug in the ground, round which stakes are driven into the earth, and thick green stakes laid across to form a kind of bed, upon which are laid abundance of dry faggots, hemp, clarified butter, and other combustibles. The widow now presents her ornaments to her friends, ties some red cotton on both wrists, puts two new combs in her hair, paints her forehead, and puts some parched rice and cowries into the end of the cloth which she wears. While this is going forward, the dead body is anointed with clarified butter and bathed, prayers are repeated over it, and it is dressed in new clothes. Ropes and another piece of cloth are spread upon the pile. The widow walks seven times round the funeral pile, strewing parched rice and cowries, and then she ascends the pile, or rather throws herself upon it.

(Ward's *Hindoos*, ii. 90; Elphinstone, *History of India; Parliamentary Papers on Suttee;* Sir John Malcolm's *Memoir of Central India.*)

SUTURE, in Surgery, is the method of sewing together the edges of wounds; and the term is also applied to the threads with which the operation is effected.

The only wounds in which the application of sutures can be beneficial are those of which the edges, if held together, are likely to unite. They are therefore improper in all contused wounds, in the majority of lacerations, and in those wounds which extend so deep that, though the superficial parts might be brought together, the deep ones would remain open. But in cleanly-cut wounds, whose edges can be placed and kept in contact without any painful stretching of the parts adjacent to them, sutures are, if applied with proper cautions, by far the most convenient and secure method of obtaining a speedy reunion.

The necessary cautions are, that they should not be allowed to remain in the wound till they excite acute inflammation, and that if from any cause the wound become inflamed, they should be at once removed. In general, thirty-six hours are sufficient for a wound through the skin and the superficial parts to unite so far that it does not need sutures to keep its edges in contact. After this time, therefore, the sutures should be removed; and in cases of deeper wounds, and of amputations, it will not be necessary to retain them more than twenty-four hours longer.

The several kinds of suture employed in surgery are named the interrupted, the uninterrupted, and the twisted. In the first, the edges of the wound, having been duly cleaned, are brought together by several single stitches placed an inch or more part. A threaded curved needle is passed through the skin from one side of the wound to the other, so as to include about one-third of an inch of healthy skin on each side of it, and then, the needle being cut off, the two ends of the thread are tied pretty firmly in a double knot over the line of the wound. This is repeated as many times as the length of the wound requires, and the spaces between the successive sutures, where the edges of the wound usually gape a little, may be held together by sticking-plaster. The latter alone will suffice when the sutures are removed.

In the uninterrupted or glover's suture, a single thread is carried alternately from one side to the other along the whole length of the wound, the needle being in each stitch passed from the border of the wound towards the adjacent healthy skin. There are only two kinds of cases in which this mode of suture can be usefully employed, namely—first, in certain wounds of the stomach and intestines, when those organs are to be returned into the abdomen, and it is of the highest importance that every part of the opening into them should be closed, so that their contents may not escape; and secondly, in ordinary cuts of the palm of the hand or the fingers, where, the cuticle being thick, the uninterrupted suture may be made without pain.

The twisted suture is employed for wounds in those parts of the skin which are very loose, and in which it is desirable to obtain a very exact union by the first intention, such as the lips, the eye-lids, the cheeks, &c. Instead of threads, one or more pins are passed across the wound and through the adjacent skin; and the edges of the former being brought together, are retained in their places by coils of silk wound like the figure 8 upon the projecting ends of the pins. This is the mode of suture commonly employed after the operation for hare-lip. [HARE-LIP.]

With all kinds of sutures it is of the highest importance that the dressings over them should be very light and cool. It is probably owing to the neglect of this caution, and of that already given respecting the time during which they should be retained, that some surgeons have been led to regard sutures as more mischievous than beneficial, ascribing to them the injuries produced by the injudicious management of other parts of the treatment.

SWAN. In England the swan is said to be a bird royal, in which when at large in a public river or creek, no subject can have property, except by grant from the crown. In creating this privilege the crown grants a swan-mark (cygninota), for a *game* of swans, called in law Latin deductus (a pastime, un déduit) cygnorum, sometimes volatus cygnorum. (7 Coke's 'Rep.,' 17.) In the reign of Elizabeth, upwards of 900 corporations and individuals had their distinct swan-marks, some of which may be seen in Yarrell's 'British Birds,' vol. iii., 121, &c.

Sometimes, though rarely, the crown, instead of granting a swan-mark, confers the still greater privilege of enjoying the prerogative right (within a certain district) of seizing white swans not marked. Thus the abbot of Abbotsbury in Dorsetshire had a game of wild swans in the estuary formed by the Isle of Portland and the Chesil Bank. The swannery at Abbotsbury is the largest in the kingdom; though formerly considerably more extensive, it still numbers many hundreds of these birds. It is now vested in the earl of Ilchester, to whose ancestor it was granted on the dissolution of the monasteries. (7 Co. 'Rep.,' 17; Hutchins, 'Dorset,' i. 538.)

The privilege of having a swan-mark, or game of swans, is a freehold of inheritance, and may be granted over. But by 22 Edw. IV., c. 6, no person, other than the king's sons, shall have a swan-mark, or game of swans, unless he have freehold lands or tenements of the clear yearly value of five marks (3*l.* 6*s.* 8*d.*), on pain of forfeiture of the swans, one moiety to the king, and the other to any qualified person who makes the seizure. In the first year of Richard III. the inhabitants of Crowland in Lincolnshire were exempted from the operation of this act upon their petition setting forth that their town stood "all in marsh and fen," and that they had great games of swans, "by which the greatest part of their relief and living had been sustained." (6 'Rot. Parl.,' 260.)

Two of the London Companies have games of swans, the Dyers' and the Vintners' Company, and are, with the crown, the principal owners of swans in the Thames. The swan-mark of the Dyers' Company is a notch, called a "nick," on one side of the beak. The swans of the Vintners' Company, being notched or nicked on each side of the beak, are called "swans with two *nicks*," whence by corruption the term which has been long used as a sign by one of the large inns in London, "swan with two necks."

On the first Monday in August in every year the swan-markers of the crown and the two Companies of the city of London used to go up the river for the purpose of inspecting and taking an account of the swans belonging to their respective employers, and marking the young birds. In ancient documents this annual expedition is called swan-*upping*, and the persons employed are denominated swan-*uppers*. These are still the designations used amongst the initiated, though popularly corrupted into swan-*hopping* and swan-*hoppers*.

The king had formerly a swanherd (magister deductus cygnorum, 'Rot. Parl.,' 16 R. II.; 4 'Inst.' 280) not only on the Thames (6 'Rot. Parl.,' 1 H. VII., fo. 359), but in several other parts of the kingdom ('Abb. Rot. Original.,' 266 b; 'Cal. Rot. Pat.,' 174 a).

Stealing swans marked and pinioned, or unmarked, if kept in a mote, pond, or private river, and reduced to tameness, is felony. (Hale, 'Pleas of the Crown,' 68.) Stealing swans not so marked or so kept, or so pursued, is merely a trespass or misdemeanor. (Dalton's 'Justice,' c. 156.)

Under the 11 Henry VII., c. 17, stealing the eggs of swans out of their nests was punished by imprisonment for a year, and a fine at the king's pleasure. But this enactment was superseded by the 1 Jac. I., c. 27, § 2, which declares that every person taking eggs of swans out of their nests, or wilfully breaking or spoiling them, may upon conviction before two justices be committed to jail for three months, unless he pay to the churchwardens for the use of the poor 20*s.* for every egg; or, after one month of his commitment, become bound, with two sureties in 20*l.* a-piece, never to offend again in like manner. And see 'Calend. Rot. Pat.,' 153 b, 165 b, 166 a, 168 a.

The 2 Henry IV., c. 21, which directs that no lord shall give any livery or sign to any knight, esquire, or yeoman, contains a proviso, that the prince may give his honourable livery of the *Swan* to his lords, and to gentlemen his menials. (3 'Rot. Parl.,' 478 a.)

(See Blomfield's *Norfolk;* Kemp's *Losely MSS.;* *Archæologia*, vol. xvi.; Colonel Hawker.)

SWEARING, a profane use of the name of the Deity. By the 109th canon, churchwardens are to present those who offend their brethren by swearing, and notorious offenders are not to be admitted to communion until they are reformed. Profane cursing and swearing were first made an offence punishable by law by 20 J. I., c. 21 (continued by 3 Ch. I., c. 4; 16 Ch. I., c. 4; and 6 & 7 W. III., c. 11). By the 19 G. II. c. 21, it is recited that these vices were become so frequent, that "unless speedily and effectually punished, they may justly provoke the divine vengeance to increase the many calamities these nations now labour under," and the statute accordingly enacts that if any person shall profanely curse or swear, and be convicted thereof on confession, or on the oath of one witness, before any magistrate, he shall forfeit, if a day-labourer, common soldier, sailor, or seaman, 1*s.*; if any other person under the degree of gentleman, 2*s.*; if of or above the degree of a gentleman, 5*s.*; for every second conviction double, and for every third and subsequent conviction treble. The penalties are to go to the poor of the parish. If the offence is committed in the hearing of the magistrate, he may convict without further proof. Parties who do not pay the penalties and costs may be imprisoned and kept to hard labour ten days for the penalties, and six other days for the costs. Magistrates and constables are liable to penalties if they wilfully omit to do their duty under the act. No person can be prosecuted except within eight days after he has committed the offence.

SWEATING-SICKNESS. *Ephemera Sudatoria, Ephemera Maligna, Sudor Anglicus, Hydronosus*, are the various names which have been given to a severe epidemic disease that prevailed in this country and in some parts of the Continent at different periods during the latter part of the 15th and the beginning of the 16th centuries. The invasion of this disease was generally quite sudden, some persons experiencing a sensation as of a hot vapour extending over the body, while others felt as if consumed by an internal fire; there was violent fever, pain in the head and limbs, prostration of strength, hurried breathing, a small frequent pulse, nausea, great thirst, delirium, and excessive restlessness. Shortly after the appearance of these symptoms a profuse clammy fetid perspiration broke out over the whole body; the thirst became more intolerable, and the patients either died in a state of delirium or coma, or recovered as suddenly as they had been first attacked. Such was the rapidity with which this disease ran its course, that its victims were sometimes carried off in three or four hours, or even before the sweating stage had set in; and all danger was considered to be at an end if the patient survived the first twenty-four hours. The profuse sweating which characterised the disease was looked upon as an effort of nature to get rid of some morbific matter from the system, and the early appearance of this stage was, therefore, regarded as a favourable circumstance. Accordingly, when persons were attacked, it was usual to put them immediately to bed, without even removing their clothes, to enjoin absolute quietude, and to encourage the outbreak of the perspiration by heating the room, covering them well up from the air, and giving them mild cordials. If the sweating stage were tardy in appearing under the influence of these means, friction was had recourse to; and if the patient were at the same time very feeble, drinks of a more stimulating quality were administered: fumigations with storax, laurel, or juniper berries were also employed. These remedies were persisted in till the sweating was fully established. After twelve or fifteen hours the coverings of the patient were diminished, the apartment was made cooler, and the air was impregnated with the vapour of vinegar; sleeping was not allowed at this stage of the complaint unless the pulse was strong, it having been observed that those who indulged in this propensity seldom woke again. At the end of twenty-four hours the linen was all changed, nourishing food was gradually administered; and on the second or third day, if the weather was propitious, the patients were allowed to go out. This mode of treatment, which is so different from that pursued in the present day in analogous diseases, does not appear to have been adopted simply with the view of hastening the accession of the sweating stage, but from the experience of the injurious influence of cold in this disease, several fatal cases having been attributed to the mere exposure of the patient's arms to the air while in bed.

The sweating-sickness is said to have made its first appearance in this country in the army of the earl of Richmond, on his landing at Milford Haven in the year 1485. On the 21st of September of the same year it reached London, where it raged till the latter end of October. It reappeared in this country during the summers of 1506, 1517, 1528, and 1551. From 1525 to 1530 it visited Holland, Germany, Denmark, Sweden, Poland, and parts of Russia; and Forestus informs us (lib. vi., obs. 8) that it broke out in Amsterdam on the 27th of September, 1529, where it raged but four days, sparing only old people and children, and attacking above one hundred persons a day. With respect to the mortality of this disease accounts are somewhat vague. Bacon informs us that in the first epidemic the patients recovered if they were attended to in time, but that many died before a remedy was discovered. The epidemic of 1517 appears to have been particularly fatal, frequently destroying its victims in two or three hours, and in some places carrying off one-third, and even one-half of the inhabitants: that of 1528 was also very fatal, but was remarkable for its short duration in each place. The last outbreak of this disease in England happened at Shrewsbury in the year 1551, and was extremely fatal, sparing neither age nor sex: it raged from April to September, becoming milder in character towards its termination.

The origin and causes of this singular malady are still involved in considerable mystery. Bacon speaks of it as a terrible and unknown disease, that had its origin neither in the blood nor in the humours; a surprise of nature, rather than obstinate to remedies. Drs. Caius and Mead believed it to be a modification of the plague; and Dr. Mead says that it was imported into this country from France, whither it had been conveyed in 1480, from the island of Rhodes, at that time besieged by the Turks. Caius affirms that the two epidemics of 1517 and 1528 were brought to England from Florence and Naples, at which places the plague was then raging, and that it was the same disease, only modified by climate. Dr. Cullen thought it a variety of typhus; and Dr. Willan suggested that it might have been produced by some disease in the wheat at those periods at which it prevailed, just as the Asiatic or malignant cholera has been attributed to the eating of bad rice. Opinions are not less at variance respecting the antiquity of this disease, and its identity with that which still prevails on some parts of the Continent, to which the term of "La Suette" has been applied. M. Rayer, without giving a decided opinion on the subject, admits that although there are notable differences between the two diseases in point of duration and gravity, yet there is an incontestible analogy between them. It is perhaps impossible at this distance of time to decide the question: we shall therefore conclude this article by referring those who may feel an interest in the subject to M. Rayer's 'Histoire de l'Epidémie de la Suette-Miliare qui a régné en 1821, dans les Départemens de l'Oise et de Seine-et-Oise,' 8vo., Paris, 1822.

SWELL. [Organ.]

SWIFTEST PROPAGATION. [Undulatory Theory.]

SWORD MANUFACTURE. Weapons of offence were early fabricated by the cutlers of Sheffield. Holland ('Manufactures in Metal') gives a representation of two men grinding a sword-blade, copied from a manuscript psalter, written about the time of King Stephen, which is preserved in the library of Trinity College, Cambridge, and which probably represents the usual construction of grinding machinery at that time. The grindstone is mounted upon a horizontal axis, which one man turns by means of a crank; and the sword, which is straight and pointed, is pressed down upon its periphery by the other man, who sits on a beam above the level of the stone, so that his weight may be conveniently thrown upon the sword, to press it firmly against the stone.

But while there can be no doubt of the extensive manufacture of swords in England at an early period, the blades made in Spain and Italy, and more especially those brought from the East, bore the preeminence. The swords of Toledo were sought after on account of their admirable temper, in the time of the Moors, and even under the Romans. It has been supposed that they were indebted for their valuable qualities to some peculiar property in the water of the Tagus, which is used in tempering them. In the early period of the French invasion, the manufactory was removed to Seville, where the national junta then was; but it was found that the swords manufactured on the banks of the Guadalquivir were very inferior to those which the same workmen had made at Toledo. In the time of the crusades, and down to a much later period, Milan supplied swords of excellent quality in large numbers. But, celebrated as these and the Spanish blades deservedly were, those from the East were still more highly prized, and enormous sums were often given for them, Of all the sabres, the fame of which has reached this country, those of Damascus are by far the most noted. Very few persons indeed have seen them; and fewer still have been the instances in which the blades themselves have confirmed those strange stories about their temper which are so generally circulated, and received among persons who know but little of the nature of steel. The characteristics ascribed to the real Damascus blades are, extraordinary keenness of edge, great flexibility of substance, a singular grain and fleckiness observable upon the surface, and a peculiar musky odour given out by any friction of the blade. Their quality, undoubtedly excellent as it must be, has been greatly exaggerated; the extraordinary powers of execution attributed to Damascus blades are, in a great measure, dependent upon the strength and dexterity of the user. A gentleman who purchased one of these sabres in the East Indies for a thousand piastres, informed Mr. Holland that, although it was very flexible, and bore a fine keen edge, it could not be safely bent to more than 45° from a straight line, and it was not nearly so sharp as a razor; yet, when wielded by a skilful hand, it would cut through a thick roll of sail-cloth without apparent difficulty. The swordsman who tried it could, it appears, do nearly the same thing with a good European blade.

About the year 1689 an attempt was made to improve and extend the sword manufacture of England by the incorporation of a company of sword-cutlers for making hollow sword-blades in Cumberland and the adjacent counties. The company was empowered to purchase lands, to erect mills, and to employ a great number of German artificers; yet the project failed. Owing, apparently, to the parsimony of the manufacturers, which led them to use inferior materials, and to employ unskilful workmen, English sword-blades fell into very ill repute during the 18th century. In 1783 the sword-sellers of London, in consequence of the very bad quality of English blades, petitioned the lords of the treasury for permission to import German swords free of duty; and this circumstance, by attracting public attention forcibly to the low state of this branch of British cutlery, led to very important improvements. Mr. Gill, of Birmingham, memorialised the lords of the treasury, stating that he could make sword-blades equal to those of Germany, and requesting a fair comparison. Circumstances delayed the public trial which he desired; but in 1786, the East India Company requiring 10,000 horsemen's swords, divided their orders indiscriminately among English and German manufacturers. Owing to the exertions of Mr. Gill, by whom some of these swords were made, a comparative trial was appointed, and every sword sent in was submitted to a machine recommended by Matthew Boulton, of Soho, in which the metal was tried by forcing the sword into a curve, so as to reduce its length from 36 inches to 29½ inches. The result was that 2650 of Mr. Gill's swords bore the test, and only 4 were rejected, while of the German swords 1400 were received and 28 rejected. The extremely low state of the British sword manufacture at that time is sufficiently testified by the fact that of the blades sent by other English cutlers, 2700 were received and 1084 rejected. In addition to the above-mentioned test, Mr. Gill tried his swords by striking them flatways upon a slab of cast-iron, and edgeways upon a cylinder of wrought-iron, which they often cut through. They were so tough, although formed of cast-steel, that, after cutting a gun-barrel asunder, Gill would frequently wind the blade round it like a riband, after which it would recover its original straightness, excepting at the point. So completely did he establish the fame of his swords, that even German officers applied to him for them.

The process of manufacturing swords at Birmingham is as follows:—The material of which the blade is wrought should be cast-steel of the very best quality, and wrought with the greatest care. The bars are heated in the fire, and drawn out upon an anvil by two workmen with hammers, giving alternate strokes. When the blade is required to be concave upon the sides, or to have a reeded back, or some similar ornament, it is hammered between steel bosses or *swages*. The blade is then hardened by heating it in the fire until it becomes worm-red, and dipping it, point downwards, in a tub of cold water. It is tempered by drawing it through the fire several times until the surface exhibits a bluish oxidation, which takes place at a temperature of about 550° Fahr. The sword is then *set* to the required shape by placing it on a sort of fork upon the anvil, and wrenching it by means of tongs in the direction required to correct any degree of warping which it may have contracted during the hardening. The grinding is performed upon a stone with either a flat or fluted surface, according to the kind of blade; and as the uniformity of the temper is impaired by this process, it is subsequently restored by a slight heating, after which the blade is glazed with emery, and, if the instrument be a fine one, with *crocus martis*, after the manner of a razor-blade. The sword is then ready for the hilt or handle. Among the tests to which sword-blades are subjected, is that of bending them into a curve by pressing the side of the blade against six or eight pegs driven into a board, in such a manner that, when in contact with all the pegs, the middle of the blade may be bent six or seven inches from a straight line drawn between the point and the hilt. A further test is applied by bending them from a vertical pillar rising from a board. The temper is also proved by striking the blade smartly upon a table on both sides, and by severe strokes with the back and edge upon a block. Mr. Inglis, in his 'Spain in 1830,' describes the trials to which sword-blades are subjected at the celebrated manufactory of Toledo. Each sword is thrust against a plate in the wall, and so bent into an arc forming at least three parts of a circle; and then struck edgeways upon a leaden table with all the force which can be given by a powerful man holding it with both hands.

The British cavalry, within a recent period, have been supplied with swords superior in quality to those before in use, slightly different in shape, and lighter in weight.

Many plans have been tried for imitating the peculiar waved appearance of Damascus blades, which is commonly called *damasking*. The Oriental processes have never been satisfatorily described, although several methods have been devised in Europe for imitating the Eastern fabrics. MM. Clouet and Hachette have pointed out three methods of attaining the desired object. The first, which is still pursued by some French cutlers, consists in scooping out with a graving tool the faces of a piece of stuff composed of thin plates of steel of different kinds; and by a subsequent operation filling up the hollows, and bringing them to a level with the external faces, upon which they form a figured appearance. The second is called the method of *torsion*, and is more generally employed. It consists in forming a bundle of strips of steel, which are welded together into a bar, and twisted several times about its axis. It is repeatedly forged and twisted alternately; after which it is slit longitudinally, and the two halves are welded with their outer sides together. The surfaces of such a bar have a curious waved or watered appearance, owing to the inter-twisting of the several rods of which it is composed. The third, or *mosaïc* method, consists in preparing a bar in the way last described, then cutting it into short pieces, and forming them into a faggot; taking care in welding them together to preserve the sections of each piece at the surface of the blade. The experiments published some years since at Milan, by Professor Crivelli, show that sword-blades of excellent quality may be produced by a combination of iron and steel. A bar of malleable steel, about an inch and a half in breadth and one-eighth of an inch in thickness, is bound round with iron-wire, at intervals of one-third of an inch. The iron and steel are then incorporated by welding, and repeated additions of iron-wire are incorporated in the same way. The compound bar thus formed is then stretched and divided into shorter lengths, which are subsequently wrought into the required form, ground, and tempered. By filing semicircular grooves into both sides of the blade, and again subjecting it to the hammer, a beautiful damasked appearance is produced; and the figures or waterings are rendered visible by washing the blades with a menstruum of aquafortis and vinegar, so as to corrode the surface slightly. The process is said to have been practised successfully in Austria and Prussia.

Another way of explaining the variegated appearance of Damascus blades is that of M. Bréant. He supposes that the oriental damask is not a mixture of steel and iron, but simply cast-steel charged with a superabundance of carbon; so that, by slow cooling, two distinct combinations are formed, the first being simply steel, and the second a mixture of steel with the excess of carbon, forming a carburetted steel or cast-iron. These two compounds form a kind of crystallised surface, which, by washing with acidulated water, assumes a damasked appearance; the parts consisting of pure steel becoming black, while the carburetted steel remains white.

Besides the numerous contrivances for producing the variegated appearance of Damascus blades, ingenious processes are resorted to for ornamenting sword-blades by etching and embossing, and by inlaying them with gold and silver wire, an art to which the name of *damascening* is sometimes applied. In the article DAMASCENE WORK, this process is noticed.

SWORDS. *Greek Swords.* The earliest and fullest information on the subject of the Greek swords is in the poems of Homer. With him the *ξίφος*, *ἄορ*, and *φάσγανον* are synonymous terms: the *μάχαιρα* is a large knife suspended near the *ξίφος* ('Il.,' iii. 271) for the purpose of cutting anything; the *ξίφος* is called *μελάνδετον*, a term not very satisfactorily explained, and *ἀργυρόηλον*, or studded with silver, an epithet relating probably to the handle (*κώπη*), which is said to be of silver: the scabbard, *κολεὸς*, in later writers called *θήκη* ('Od.,' viii. 404), is covered with ivory.

At a later period coins, vases, and other ancient monuments, exhibit the form of the Greek sword, which was a short cut-and-thrust blade, diminishing gradually from hilt to point.

Varieties in the form of the blade and handle are occasionally to be met with on vases. (Millin., 'Vases Antiques,' pl. 26 and 56.) The *θήκη*, or scabbard, sometimes terminates in a knob, the *μύκης* probably of Herodotus (iii. 64). We have only scanty and incidental notices of the sword in Greek writers after the time of Homer. C. Nepos ('Iphicrates,' c. i.) records that that general introduced a longer sword among the Athenian infantry. Xenophon ('De Re Eques.,' xii.) prefers the *μάχαιρα* to the *ξίφος* for cavalry, because their position on horseback he considers more favourable for the cutting than thrusting: in this passage *μάχαιρα* is used synonymously with *κοπίς*, which leads us to suppose it to have been made at that time only for cutting. In later writers the terms *μάχαιρα* and *ξίφος* are used indiscriminately. (Polyb., iii. 114.)

The Greek sword was worn on the left side, suspended by a belt generally from the shoulder, as in the figure of Meleager on the coins of Ætolia, but occasionally by a girdle round the waist. On a vase in Millingen (pl. 23) it is slung more forward, so that the hilt is in the middle of the breast. The material of the Greek blade was generally bronze; in later times, iron.

Roman Swords.—The Roman sword was called "ensis," "gladius," and "mucro" (though "mucro" originally meant the point of the sword only; its edge, "acies;" its handle, "capulus;" its scabbard, "vagina"). Polybius gives an accurate description of the Roman sword used in his day, which had the Iberian short straight cut-and-thrust blade of finely tempered steel: this had been substituted for the old Roman sword at the time of the war with Hannibal (lib. vi.; also 'Fragm.,' xiv., where he speaks of the admirable temper of the Celtiberian blades). The form of the sword continued from his time till that of the later emperors, apparently unchanged. Montfaucon ('Antiquités,' vii.) states that the blades of those on the column of Marcus Aurelius and the arch of Severus are more pointed than on the column of Trajan, and that they became shorter in the time of Constantine the Great and Theodosius. Stewechius ('Comment.' in Vegetium, p. 64, Vesal., 1670) speaks of a larger kind of sword, "spatha," under the later emperors. There seems to be no distinction in size or shape between the swords of the infantry and cavalry on Trajan's column and other similar monuments. The sword used by the gladiators was somewhat curved. The Roman sword was worn on the right side. Montfaucon notices three exceptions to this general practice on the arch of Septimius Severus; and the spathæ already mentioned are said to be worn on the left side. The parazonium appears to have been the insigne or sword of office of a military tribune. (Martial, xiv. 29; Raderus, 'Comment.,' in loc.; and Pitisc., 'Lexicon Antiq. Roman.')

Other Ancient Swords—For the swords of other nations of antiquity, see Wilkinson's 'Antient Egyptians;' for the Assyrian, the works of Layard and Botta; for the ἀκινάκης, or Persian sword, and that of other Eastern people, Leake, 'Athens,' ii.; and for the swords of the Gauls, Livy, xxii. 46, and Diodorus, v. 30.

In the British Museum are four ancient bronze swords, three of which have cut-and-thrust blades, varying in length from 10 to 25 inches, and in breadth from 1¼ to 2 inches. Another, considered to be Etruscan, is bound with gold wire round the handle, and is about 13 inches long. In Montfaucon ('Antiq.,' vii.) are engravings of three, two of which, as he states, measured a foot and a half (French), and the other 30 inches in length. In the Museo Borbonico, vol. v., pl. xxxix., is an engraving of one having two rings on its scabbard, which is of wood, covered with plates of metal, and studded with brass; a handle of another is finished with an eagle's head, and other varieties are shown in the same work.

SYLLABLE (συλλαβή). A syllable consists of one or more elementary sounds of a language uttered in one emission of voice. The pronoun *I* is an example of a syllable consisting of but one elementary sound; and the syllable *strange* is an example consisting of several elementary sounds articulated (joined) together. Words which consist of one syllable are termed monosyllabic; those consisting of two are termed dissyllabic; those of three, trisyllabic; and those of more than three are indefinitely termed polysyllabic.

Spoken language is a system of audible signs for the expression of thought, and written language is a system of signs to express spoken language, so that written language is two removes from thought. Syllables, both as words and as parts of words, belong both to spoken and written language.

In a pronounced syllable two distinct things are observable, namely, 1st, its elementary structure; and, 2nd, the musical properties of the voice, consisting of those distinctions of sound which are described under the general terms pitch, loudness, and quality. Thus in the pronoun *I* we observe the elementary structure to be the diphthongal vowel *I*, as heard in the word *isle*; and we observe also whether the syllable be said or sung, that is, whether the condition of voice belongs to speech or to song: an accurate observer also perceives the precise degree of pitch and loudness and the character of the quality of voice.

The time which a syllable occupies in pronunciation is termed its quantity. In solemn and stately discourse the quantities of syllables are extended beyond their ordinary length; while in rapid colloquy they are somewhat shortened. The ordinary quantity of a syllable, when neither extended nor protracted, is the sum total of the quantities of its constituent elementary sounds: thus the quantity of the syllable *nine* is the sum total of the quantities of its elementary sounds *n*, *i*, of *isle*, and *n*.

In words of more than one syllable, one of them is always made more conspicuous to the ear than the other, by what is termed stress or accent. Stress is produced either by an abrupt percussion of voice, as in the word *pepper*, or by an extended quantity on a swelling loudness of voice, as in the word *amaze*. The stressed syllable of a word is invariably that which receives the modification of voice expressive of sense and feeling, called emphasis.

The metrical arrangement of language depends on the quantity and stress of syllables, both of which are inherent; while the pitch, loudness, and quality of voice in which the syllables are uttered are accidental, and belong to the thought and feeling of the speaker.

Dividing words into syllables is a different operation according to the object in view, thus: 1. When a word is pronounced in widely separated syllables, to enable a child to appreciate each, as in uttering the word *provided*, thus, *pro-vi-ded*, by which means a child readily apprehends each successive syllable of the word; 2. When a word is analysed into its component parts, in order to exhibit its etymology, and thus lead to a clear apprehension of its signification, as a whole from knowing that of its parts, as in dividing the word *thermometer*, thus, *thermo-meter*; 3. To divide a word into its syllables, to enable another to write it with correctness, as the word *barometer*, thus, *ba-ro-me-ter*.

SYLLOGISM (συλλογισμος). The object and character of logic are explained under the word ORGANON; the position of this article in the present work is explained in LOGIC. Every sentence in which different assertions are combined to produce another and a final assertion, is either a syllogism, a collection of syllogisms, or a mass of words without meaning; and when we separate the constituent assertions, and write the whole under the forms of logic, we are not thereby ceasing to consider the sentence which contains those assertions, or, as many fancy, dealing with a new species of ratiocination. All that is called reasoning, and which cannot be made syllogistic, is not reasoning at all; and all which cannot easily be made syllogistic, is obscure; for the syllogism is the simple form in which the act of reasoning is an act of intuition.

Aristotle defines syllogism thus: "Syllogism is speech or language in which certain things being assumed, something different from what is assumed results by virtue of the assumption; and, by virtue of the assumption, I mean it results through the assumption; and, by 'through the assumption' I mean that no external term is required in order to there being a necessary result." ('Analyt. Prior.' i. 1.)

So easy indeed is the deduction, when the premises are properly disposed as preparatory to a syllogism, that many persons doubt the utility of the syllogism altogether. With these we are not now arguing; we shall only observe that he must be fortunate in the clearness of his mind, who, knowing the logical mode, is never obliged to have recourse to it to destroy ambiguity or heighten evidence; and particularly so in his opponents, who, in verbal or written controversy, never finds it necessary to employ it in trying their arguments. The syllogism is the instrument of self-examination, and the weapon of last resort in dispute; and a bad syllogism, with one of the premises implied only, and not expressed, is the first resource of fallacy; which last is sometimes even allowed to remain unrefuted, by neglect of placing it in a logical form. To bring forward the suppressed premiss is the visible destruction of every such argument which is logically bad. As an instance, take the following in a letter from Cardan to Tartalea: "Neither am I moved with envy, *for* if you are either equal to, or less than myself, I have no cause for it; and, if you be greater in this art, I ought to endeavour to equal you, and not to speak evil of you." This is meant for reasoning, and there are two syllogisms with suppressed premises, or rather two sorites (a term presently explained), with a suppressed premiss in each. In one case Cardan assumes that he does not envy Tartalea because he *need* not; in the other, that he does not because he *ought* to do otherwise: if he meant to assume and assert that he never did anything which he had no need to do, and always did everything which he ought to do, his reasoning is logical; but if he would have hesitated to make these assertions, he was then writing fallacy. In justice to Cardan's logic, however, it is but fair to say, that he was not the man to hesitate at either assertion. [CARDAN, in BIOG. DIV.]

Every sentence in which the conclusion is a necessary consequence of previous assertions contained in that same sentence, is a syllogism, provided that the conclusion be obtained from two distinct assertions, and two only. Thus, "Some As are Bs, for every B is A,' is not a syllogism, though logically true. [CONVERSE.] Every assertion may be reduced to one of four forms, the universal affirmative, the universal negative, the particular affirmative, and the particular negative. From these, by combination, all syllogisms are derived; and the laws of combination, and the manner of expressing them, constituted that branch of science which is now often turned into ridicule, particularly as to its notation, and the strange and uncouth words by which the species of syllogisms were denoted. The following letters always signify the several species of propositions:—

A, the universal affirmative; every X is Y.
E, the universal negative; no X is Y.
I, the particular affirmative; some Xs are Ys.
O, the particular negative; some Xs are not Ys.

Since every conclusion must be drawn from the comparison of two things with a third, a syllogism consists of two propositions, in each of which the same term occurs compared with another: this term is called the *middle term*. Thus, in

Every Y is X,
Every Z is Y,
Therefore Every Z is X,

Y, the subject of the first assertion, and the predicate of the second, is the middle term. The two first assertions are the *premises*, the third is the *conclusion*. The predicate of the conclusion is called the *major term*; the subject of the conclusion the *minor term*: and the major or minor premiss is that which contains the major or minor term of the conclusion. The major premiss is always written first.

The order of the terms in the premises and conclusion must be either

I.	II.	III.	IV.
YX	XY	YX	XY
ZY	ZY	YZ	YZ
ZX	ZX	ZX	ZX;

and these are called the four *figures*. The three first are in Aristotle, the fourth was by tradition ascribed to Galen, and was called Galenic. In the first figure the middle term is the subject of the major, and the predicate of the minor; in the second, the predicate of both; in the third, the subject of both; in the fourth, the predicate of the minor and the subject of the major. Every particular case of a figure is called a *mood*; and since either of the premises may be either of the four species of propositions, A, E, I, O, it follows that there are sixteen moods in each figure, or sixty-four possible moods in all. But of these, many are inconclusive, and many moods which admit of conclusion in one figure do not in another. Thus, the mood in the example above is AA, and if we apply it in the four figures, we have—

Every Y is X	Every X is Y	Every Y is X	Every X is Y
Every Z is Y	Every Z is Y	Every Y is Z	Every Y is Z.

The first has a conclusion: every Z is X. The second has none; that is, for anything to the contrary contained in the premises, we may either say every Z is X, no Z is X, some Zs are Xs, or some Zs are not Xs.

It also admits every X is Z, but here Z is the major term, and not X. The third admits a conclusion: some Zs are Xs. The fourth also admits a conclusion: some Zs are Xs. Consequently, the first figure has a syllogism AAA, the third and fourth have AAI.

If all the sixty-four cases be examined (a most useful exercise), it will be found that the following syllogisms are valid. We arrange them first by figures, then by moods :—

First Figure : AAA, EAE, AII, EIO.
Second Figure : EAE, AEE, EIO, AOO.
Third Figure : AAI, IAI, AII, EAO, OAO, EIO.
Fourth Figure : AAI, AEE, IAI, EAO, EIO.

The following is the statement by moods :—

$(AA)A_1I_3I_4$, $(AE)E_2E_4$, $(AI)I_1I_3$, $(AO)O_2$
$(EA)E_1E_2O_3O_4$, $(EI)O_1O_2O_3O_4$,
$(IA)I_3I_4$,
$(OA)O_3$.

Here, for instance, we express by $(IA)I_3I_4$ that the mood IA never proves anything but I, and that only in the third and fourth figures. From the preceding we may collect that—

As to figures: any proposition may be proved in the first; none but negatives in the second; none but particulars in the third; and everything but the universal affirmative in the fourth.

As to moods: from premises both negative or both particular, no conclusion follows: where one premiss is negative, the conclusion is negative; and where one premiss is particular, the conclusion is particular.

In order to remember the figures certain words have been long used by writers on logic, which make a grotesque appearance; but if the reader will tolerate them till we have gone through an example of each syllogism, he shall see that those who made them were at least as good wits as those who laugh at them. The magic words of the fourth figure are different in different writers; we have taken those used by Dr. Whately.

First Figure : Barbara, Celarent, Darii, Ferio.
Second Figure : Cesare, Camestres, Festino, Baroko.
Third Figure : Darapti, Disamis, Datisi, Felapton, Bokardo, Feriso.
Fourth Figure : Bramantip, Camenes, Dimaris, Fesapo, Fresison.

Thus the vowels AAA are seen in *Barbara*, AII in *Datisi*. The following are instances of each form, with an example which may easily be reduced to the form.

First Figure.

Barbara.—Every Y is X, every Z is Y, therefore every Z is X. *Example.* They must, as men, have faults: or all men have faults, these persons are men, therefore these persons have faults; strictly, all men *are* persons having faults, &c.

Celarent.—No Y is X, every Z is Y, therefore no Z is X. *Example.* Those who bribe should not, any more than any other lawbreakers, be exempt from punishment.

Darii.—Every Y is X, some Zs are Ys, therefore some Zs are Xs. *Example.* Exploded doctrines are sometimes true, because capable of proof.

Ferio.—No Y is X, some Zs are Ys, therefore some Zs are not Xs. *Example.* Some of the earlier principles of science are not well appreciated for want of attention to the usual modes of operation of the mind.

Second Figure.

Cesare.—No X is Y, every Z is Y, therefore no Z is X. *Example.* The presence of horns in this species, and their absence in the other, is a complete distinction between the two.

Camestres.—Every X is Y, no Z is Y, therefore no Z is X. The last example will do: this mood is only a consequence of the convention by which the major premiss is to be written first, and of the convertibility [CONVERSE] of the universal negative proposition.

Festino.—No X is Y, some Zs are Ys, therefore some Zs are not Xs. *Example.* Persons who pretend to form an opinion on philosophical subjects are oftentimes incapable of doing it properly, from want of acquaintance with the exact sciences. This example is given purposely, as falling more naturally into another figure, though capable of expression in this.

Baroko.—Every X is Y, some Zs are not Ys, therefore some Zs are not Xs. *Example.* None but the industrious can succeed, so that there must be many failures.

Third Figure.

Darapti.—Every Y is X, every Y is Z, therefore some Zs are Xs. *Example.* Politics and literature are not necessarily incompatible, for many persons can be named who have cultivated both.

Disamis.—Some Ys are Xs, every Y is Z, therefore some Zs are Xs. *Example.* Many things inexpedient, because wrong, are apparently useful.

Datisi.—Every Y is X, some Ys are Zs, therefore some Zs are Xs. The last example will do for this also.

Felapton.—No Y is X, every Y is Z, therefore some Zs are not Xs. *Example.* There are organised bodies to whose existence air is necessary, and which have no locomotive power, as plants, for instance.

Bokardo.—Some Ys are not Xs, every Y is Z, therefore some Zs are not Xs. *Example.* Even industry does not always succeed, for men of great research have been mistaken.

Feriso.—No Y is X, some Ys are Zs, therefore some Zs are not Xs. *Example.* It is not true that all who gave evidence were present, for A, B, C, &c., were many miles off.

Fourth Figure.

Bramantip.—Every X is Y, every Y is Z, therefore some Zs are Xs. *Example.* Among repulsive things are the sciences themselves, for they are all difficult.

Camenes.—Every X is Y, no Y is Z, therefore no Z is X. *Example.* No perfect being can be man, for all men are subject to decay, the unfailing mark of imperfection. This example would do very well as one of the most common species of fallacy, that in which the middle term is used in different senses, so that there is in fact no middle (or *common* middle) term. We have seen this argument used somewhere, "perfect being" meaning "*morally* perfect being," and "imperfection" including *physical* as well as *moral* imperfection.

Dimaris.—Some Xs are Ys, every Y is Z, therefore some Zs are Xs. *Example.* Some writers who repeat themselves are amusing, for every prolix writer does it, and the most attractive books are not always the shortest.

Fesapo.—No X is Y, every Y is Z, therefore some Zs are not Xs. *Example.* Some things which are not much written about are not worth learning; not that this circumstance is otherwise an index, except in this manner, that all really useful learning has its opponents, and it is only where there is opposition that much discussion ever takes place. Here is a good instance of the case in which the premises both yield the conclusion, and explain the sense in which it is to be taken: the preceding is no syllogism unless the "writing about" the subject in the conclusion mean writing about not the subject itself, but whether it be useful or not.

Fresison.—No X is Y, some Ys are Zs, therefore some Zs are not Xs. *Example.* Some things which are cried up can hardly be relics of antiquity, for they are valueless. Here is an instance of an argument which, logically undeniable, may be disputable as to the *matter*. One of the premises is "no relic of antiquity is valueless," which many may be found to deny.

Some other forms have been given, but they are only some of the preceding with the premises transposed, and which, therefore, do not obey the conventional rule relative to the precedence of the major premiss: as, for instance, one named *Baralipton* (AAI, the last syllable being only a termination) which we may mention particularly, inasmuch as this word has been very often quoted as a specimen of logical terms. It runs as follows:—Every Y is X, every Z is Y, therefore some Xs are Zs. Transpose the premises, and we have the first syllogism of the fourth figure.

Of all the four figures the first is the most natural, and every mood of the other three can be reduced to one of the first, in one of the following ways. It will be seen that every name in the last three figures begins with one of the initial letters of the first, and thus it is pointed out to which mood of the first figure each is reducible. Thus Cesare, Camestres, and Camenes are those which are reducible to Celarent of the first figure.

The other significant letters of the descriptive words are *m*, *s*, *p*, *k*, wherever they occur. By *m* it is implied that the premises are to be transposed; by *s* that the premiss marked by its preceding vowel is to be converted, whence *s* follows only E and I [CONVERSE]; by *p* that the conversion is to be made in a limited manner, or *per accidens* [CONVERSE]; and by *k* that the reduction is made by what is called the *reductio ad impossibile*, a term which we now explain. It means that the syllogism can be replaced by one in the first figure, which proves, not the truth of the conclusion, but the falsehood of its contradictory. [CONTRARY AND CONTRADICTORY.] For example, take the syllogism *Baroko*, or

Every X is Y,
Some Zs are not Ys,
Therefore Some Zs are not Xs.

If the conclusion be denied, it must be by affirming that every Z is X. Let this be so, then we must have the syllogism *Barbara* as follows :—

Every X is Y,
Every Z is X,
Therefore Every Z is Y.

But, by hypothesis, some Zs are not Ys, whence this conclusion contradicts one of the admitted premises, or must be false. One, then, of the premises which gives it must be false; but since Every X is Y is supposed true, it must be Every Z is X, which is false, or Some Zs are not Xs, which is true. This is a specimen of the persevering determination of the older logicians to make everything reducible to the first figure.

It appears then that few words have ever been invented which have really so much meaning as the now despised appellations of syllogisms. Take, for example, *Disamis*; every letter is a sentence. D means that the mood of the first figure into which this can be reduced is Darii; I, that the major premiss is a particular affirmative proposition; S, that the reduction requires the major premiss to be simply converted A, that the minor is a universal affirmative; M, that the reduction requires the transposition of the premises; I, that the conclusion is a particular affirmative; S, that the conclusion must be simply converted. We thus change

DISAMIS. DAR
Some Ys are Xs, ⎫ ⎧ Every Y is Z,
Every Y is Z, ⎬ into ⎨ Some Xs are Ys,
Some Zs are Xs, ⎭ ⎩ Some Xs are Zs.

A *proper* mood was one in which one of the premises spoke of a single subject, as in "All Frenchmen talk French, Pierre is a Frenchman, therefore Pierre talks French." There was much discussion as to whether such a proposition as "Pierre is a Frenchman" was a universal affirmative or not, it being obvious on all sides that, whether or no, it would have in deduction all the properties of a universal affirmative.

An *enthymeme* is a syllogism in which one premiss is obviously implied, and is the form in which argument is commonly given. For example, "He isn't here; I don't see him," implies that the speaker would affirm himself certain of seeing him if he were there, and is an enthymeme which, with the suppressed premiss restored, makes the following syllogism :—

Fig. 2. A All that is here is seen by me.
Camestres. E He is not seen by me.
Therefore E He is not here.

The *sorites* is a collection of *Barbara* syllogisms, in which the suppressed conclusion of the first is a premiss of the second, that of the second a premiss of the third, and so on; as in A is B, B is C, C is D, D is E, therefore A is E. Here are three syllogisms, namely,

A is B	A is C	A is D
B is C	C is D	D is E
A is C	A is D	A is E

Various attempts were made to classify the manners in which common argument is to be expressed syllogistically. The only difficulty is to reduce the expressions to the pure form of simple assertion or negation. An oblique syllogism was one in which one of the oblique cases enters the premises in such a manner as to vitiate the purity of the form. For instance,

The thoughts of man govern his actions,
John is a man,
Therefore John's thoughts govern his actions.

As it stands, this is not strictly a syllogism, and some less idiomatic expressions must be adopted before it can be turned into one. As,

(Every man) is ⎧ a being whose thoughts
⎩ govern his actions,
John is a man,
Therefore John is a being, &c.

The same thing occurs in a *modal syllogism*, which is one in which some modifying expression gives more or less of force to one or both premises. As

Probably Every Y is X,
Every Z is Y,
Therefore Probably Every Z is X.

If we consider both matter and form, we have here merely a syllogism in which one premiss is only probable. [PROBABILITY.] But, considering form only, the perfect deduction may be made as follows :—

Every Y is ⎧ a thing which is more likely than
⎩ not to be X,
Every Z is Y, therefore every Z is [a thing, &c.]

The *inductive* syllogism is merely one in which one of the premises is proved by induction, or by separate proof of every instance: as when the Ys are known to be A, B, and C, and no more, and Every Y is X is shown by proving separately that A is X, B is X, C is X. There is nothing peculiar to the syllogism here. [INDUCTION.]

The *hypothetical* syllogism (so called) is one in which the truth of one proposition is stated to depend solely on that of another; so that the first can be affirmed as soon as the second is known to be true, or the second can be denied as soon as the first is known to be false. Thus,

If A be B, C is D,
But A is B, therefore C is D.
Or, If A be B, C is D,
But C is not D, therefore A is not B.

Whenever a proof is complete, except in one proposition—when, for example, we have fully made out that C is D, except only in this that the proposition "A is B" is not yet proved, the first member of the hypothetical syllogism lays down the state of the argument. When all that will prove a proposition is true, the proposition itself is true, whence there is only need to affirm the one doubtful premiss, to make the conclusion a logical consequence. Again, when a proposition is false, some part of any logical proof must be deniable: hence there is only need to deny the conclusion in order to make the one doubtful premiss logically deniable.

The *conditional* syllogism is reducible to an hypothetical one. It is when, under certain circumstances, the first member affirms a proposition, as in Wherever A is B, C is D.

The *dilemma* is a double or other compound syllogism, in which two or more contradictory propositions form each a conclusion with other propositions, so that from those other propositions necessarily follows one or other of the conclusions; because of contradictory propositions one must be true. It is not therefore a syllogism, but a collection of them. For example, "He must either have been for, against, or neuter: if for, he was unjust; if neuter, he was mean; if against, he was false; therefore he must have been either unjust, mean, or false." This presumes the existence of a premiss for each conclusion; as for example, that the cause is that of oppression, that he is so circumstanced that nothing but fear or favour could prevent him from taking part with the right, and that he has pledged himself to the wrong.

The rules of syllogism may be briefly condensed as follows :—

1. One at least of the premises must be affirmative, and one at least universal; 2, the middle term must enter universally in one of the premises; and 3, the conclusion must not speak of any term in a wider sense than it was spoken of in the premiss in which it entered. A term universally spoken of is either the subject of a universal affirmative, or the predicate of any negative.

The first rule is derived from observation, but might be demonstrated. The second is seen thus: if the middle term were not universally spoken of in one premise, there might be in reality no middle term, or nothing with which to compare the major and minor term. Thus if we attempt to infer anything from Every X is Y, some Ys are not Xs, we merely see that all the Xs are so many of the Ys, or make up a part of the Ys. Some of the Ys (another portion, it may be) are not Zs, so that the common term does not exist, or may not exist. The third rule is obvious, for no more can be made of any assertion than it contains, and an argument which asserts something about every X from premises which only mention some Xs, must be illogical.

The various species of fallacies must consist either in the introduction of unproved propositions, or an illogical use of those which are proved. We do not feel it necessary to extend this article by entering into the usual classification of them.

SYLVIC ACID, $(C_{40}H_{30}O_4)$ a substance which with pinic acid [PINIC ACID] constitutes the greater portion of colophony, or common rosin. When this substance is digested in cold alcohol of specific gravity 0·833, the pinic acid dissolves, but the sylvic acid remains insoluble in alcohol until it is boiled; on cooling, it separates in crystals of considerable size, the form of which, according to Unverdorben, is a rhombic prism terminated by four facets, but Laurent represents it as an acute rhomboid, the edges of which are usually serrated.

Sylvic acid melts below 212°; is insoluble in water, but dissolves readily in hot alcohol and in ether, and is precipitated by water; it is soluble also in all proportions in the volatile and fixed oils. Concentrated sulphuric acid dissolves and water precipitates it from the acid; by the action of nitric acid it is converted into another resinous acid when it has been precipitated from alcohol by water; ammonia dissolves this acid readily, and the sylvate of ammonia formed, as well as that of potash and of soda, is soluble in water; most sylvates are however insoluble in it, but many of them are dissolved by alcohol and by ether; the sylvate of magnesia especially is taken up by alcohol; the sylvates of silver and lead are colourless and insoluble in water.

SYMBOLS, CHEMICAL. [CHEMICAL FORMULÆ.]

SYMBOLS and NOTATION. The word symbol (from the Greek *sýmbolon*, σύμβολον) means "that which is taken with," and a symbol is a mark which is always attached to some one particular meaning. Notation (*nota*, a known mark) is the method of selecting and assigning meaning to symbols, and the theory of notation (if it yet deserve the name) includes the consideration and choice of symbols, with the formation of rules of selection, so as to take the symbols which are best adapted for the purpose.

This subject might be treated in a very wide manner; for all marks with understood meanings are symbols, from written words to direction-posts. A picture is a symbol, the force of which lies in the resemblance to its object, and many of the earliest symbols must have been pictorial. It is obvious that a general treatment of the subject would hardly be within the power of any one person, and that its extent would be enormous, though it would be desirable to have it discussed in a more general form than has yet been attained, in order that its different parts might receive aid from the rest. Symbols are to the progress of civilisation precisely what mechanism is to that of the arts,—not a moving force, perfectly dead in themselves, but capable of being made the medium by which the power is conveyed to its destination, and adapted to its object. They are the instruments of our first thoughts and the originators of new ones. The process by which the earliest symbols called out a yet higher intelligence than that which produced them, which last was again employed in perfecting the symbols themselves, and so on alternately, exactly resembles what has taken place in the mechanical arts. The earliest and rudest tools were first employed to make better ones; and every improvement in the use force has found one of its best applications in the construction of machinery itself.

We propose in this article to treat particularly of mathematical notation, which, like language, has grown up without much looking to, at the dictates of convenience and with the sanction of the majority. Resemblance, real or fancied, has been the first guide, and analogy has succeeded.

Signs are of two kinds: 1st, those which spring up and are found in existence, but cannot be traced to their origin; 2ndly, those of which we know either the origin, or the epoch of introduction, or both. Those of the first kind pass into the second as inquiry advances. [ALPHABET.] In our present subject we have mostly to deal with the second class.

Mathematical marks or signs differ from those of written language in being almost entirely of the purely abbreviative character, since it is possible that any formula might be expressed in words at length. We say possible, because it is barely so, not meaning thereby to imply that the mathematical sciences could ever have flourished under a system of expressions in words. A well-understood collection of notions, however extensive, becomes simple as a matter of conception by use and habit, and thus becomes a convenient resting-point for the mind and a suitable basis for new combinations of ideas. Now it is the characteristic of the advance of human knowledge that the mind never grapples at once with all that is contained in the notions under use for the time being, but only with some abstraction derived from a previous result, or some particular quality of that result. Hence no symbol which should contain the representative of every idea which occurred in the previous operations would ever be necessary; and more than this, it would even be pernicious from its complexity, as also from its suggesting details which are not required. The generalisation, or rather abstraction, which is the distinctive character of the civilised language as compared with the savage (though the latter is not wholly without it), must be the ruling process of mathematical notation, as it is of the advance of spoken language; and in this point of view the connection of our subject with speech presents more analogies and gives more instruction than its comparison with the written signs of speech. The latter is a bounded subject. When once it is agreed how the different modifications of sound shall be represented, written language follows immediately; nor do the infinite modes of using words require any modification of the method of writing them. In our modern works, for instance, it would be difficult to find many artifices of notation with which to compare the never-ceasing varieties of mathematical signs. In mentioning the marks of punctuation and reference, the italics for emphatic words, and the varieties of print by which notes are distinguished from text, &c., we have almost exhausted the list.

The greatest purposes of notation seem to be answered when the reader or learner can tell what is meant, first, with the utmost certainty, secondly, with sufficient facility; it being always understood that the second must be abandoned when it clashes with the first. Too much abbreviation may create confusion and doubt as to the meaning; too little may give the meaning with certainty, but not with more certainty than might have been more easily attained. Thus the old algebraists, in using A *quadratum* for A multiplied by A, in their transition from words at length to simple notation, used ten symbols where two only are requisite; and those who first adopted the symbol $A\,A$ lost no certainty, and gained materially in simplicity. The successors of these, again, who employed AA, AAA, $AAAA$, &c., to stand for the successive powers of A, were surpassed in the same manner by those who adopted A^2, A^3, A^4, &c. Beyond this it is obvious the notation cannot go in simplicity. The symbol which is to represent "n As multiplied together" must suggest all three components of the preceding phrase—namely, n and A, and multiplied together. In A^n, the n and A are obvious, and the position of the letters is the symbol of multiplication; but, on the other hand, those who teach the beginner to signify by A^2 the square described on the line A, purchase simplicity at the expense of certainty. The same mathematical phrase with them stands for two different things, connected indeed, but of more dangerous consequences from that very connection; for where similarities exist, the reader should not be made to convert them into identities. It is of as much importance to impress the distinction of the things signified as the analogy of their properties.

Certainty, then, and the greatest facility of obtaining it, seem to be the main points of good notation; and this is true with respect to the learner of all that has gone before. Grant that the mathematical sciences are never to advance further, and many alterations might be made, and many new practices adopted, which would give facility in acquiring the past, without any introduction of obscurity. But the future must also be thought of; and no scheme will merit approbation which enlightens one end of the avenue at the expense of the other. Notation influences discovery by the suggestions which it makes: hence it is desirable that its suggestions should be as many, as plain, and as true, as it is possible. Here we are on quite a different ground: reason is the builder and settler, but imagination is the discoverer; and it might turn out that a notation which suggests many and obvious new ideas, though some of them should be fallacious, would be preferable in its consequences to another of less suggesting power, but more honest in its indications. And while we speak of positive suggestion, it must not be forgotten that a notation may be faulty in occupying the part of the symbol which properly belongs to the extension of another notation. The latter is thus deprived of its natural direction of growth, and must find its way elsewhere, to the injury perhaps of some other part of the symbol. In throwing together a few rules, previously to a little description of the present state of mathematical notation, we do not pretend to have exhausted the list of cautions which the subject requires. It is to be remembered that the language of the exact sciences, instead of being, as should be the case, a separate subject, is hardly ever treated at all, and then only in connection with some isolated parts of the system. With the exception of an article by Mr. Babbage, in the 'Edinburgh Encyclopædia,' we do not know of anything written in modern times on notation in general. Much may be collected, having notation for its specific object, from the writings of Arbogast, Babbage, Carnot, Cauchy, J. Herschel, and Peacock, writers who all have considered it necessary, when proposing a new symbol or modification of a symbol, to assign some reason for the proposal. In general, however, it is the practice to adopt or reject notation without giving any justification of the course pursued. If it could be rendered necessary, by the force of opinion, that every author should, in making a new symbol, explain the grounds, firstly, of his departure from established usage,—secondly, of his choice from among the different methods which would most obviously present themselves,—two distinct advantages would result. In the first place, we should in most cases retain that which exists, until something was to be gained by altering it; in the second, research and ingenuity would have a call into action which does not now exist. We hardly need mention a thing so well known to the mathematician as that the progress of his science now depends more than at any previous time upon the protection of established notation, when good, and the introduction of nothing which is of an opposite character. We should rather say the rate of progress; for, however bad may be the immediate consequences of narrow and ignorant views in this respect, they cannot be permanent. The language of the exact sciences is in a continual state of wholesome fermentation, which throws up and rejects all that is incongruous, obstructive, and even useless. Had it been otherwise, it is impossible that the joint labours of three centuries and many countries, of men differing in language, views, studies, and habits, could have produced so compact and consistent a whole, as, with some defects (though no two persons agree precisely what they are), the present structure of mathematical language must be admitted to present.

The following rules and cautions, with respect to notation, are drawn from observation of the present state just alluded to.

1. Distinctions must be such only as are necessary, and they must be sufficient. For instance, in so simple a matter as the use of capitals or small letters, whatever may guide the inquirer to adopt either in one case should lead him to the same in another, unless some useful distinction can be made by the change. Thus a writer who in one instance uses a capital letter to denote a complicated function of small letters (which is a very desirable mode), will in another part of the same question employ a small letter for a similar purpose, thus nullifying an association of ideas which perspicuity would desire to be retained. If such a course were necessary in the first case, it is still more so in the second. It is not often that the second part of this rule is infringed; so small an addition makes a sufficient distinction, that the principal danger which arises is that of the same notative difference occurring in too varied senses in *different* problems.

The tendency to error is rather towards over-distinction than the contrary. It is surprising how little practice enables the beginner in mathematics to remember that so slight a difference as that of a and a' implies two totally different numbers, neither having any necessary connection with the other. The older mathematicians [ACCENT] overdid the use of distinctions by their uniform adoption of different and unconnected letters; and forgot resemblances.

2. The simplicity of notative distinctions must bear some proportion to that of the real differences they are meant to represent. Distinctions of the first and easiest order of simplicity are comparatively few; the complications of ideas of which they are the elements of representation are many, and varied to infinity. There is no better proof of skill than the adaptation of simple forms to simple notions, with a graduated and ascending application of the more complicated of the former to the more complicated of the latter. But some writers remind us in their mathematical language of that awkward mixture of long and short words to which the idiom of our language frequently compels them in their written explanations of the formulæ. For example, if there be two words of more frequent occurrence than any others, they are *numerator** and *denominator;* the parts of a fraction cannot be described under nine syllables. A mathematician will have occasion to write and speak these words ten thousand times, for every occasion on which he will have to use the word *cusp*, of four letters. A comparatively rare idea, used in an isolated subject, can be expressed in one syllable, while the never-ending notions of the parts of a fraction require nine: this he cannot help; but it is in his power to avoid the same sort of inversion in his notation.

3. Pictorial or descriptive notation is preferable to any other, when it can be obtained by simple symbols. Many instances occur in astro-

---

* These words might well be shortened into numer and denomer.

nomy, and the use of the initial letters of words may be cited as a class of examples: as in f for force, v for velocity, &c.

4. Legitimate associations which have become permanent must not be destroyed, even to gain an advantage. The reason is, that the loss of facility in reading established works generally more than compensates for the advantage of the proposed notation; besides which, it seldom happens that the desired object absolutely requires an invasion of established forms. For instance, perhaps the most uniform of all the notations of the higher mathematics is the use of the letter d to signify an increment which is either infinitely small, or may be made as nearly so as we please. A few Cambridge writers, some years ago, chose to make a purely arbitrary change, and to signify by dy, dz, &c., not increments, but limiting ratios of increments: and students trained in their works must learn a new language before they can read Euler, Lagrange, Laplace, and a host of others. Thus d_xy has been made to stand for $dy : dx$, and the old association connected with dy has (in the works spoken of) been destroyed. Now if the letter D had been employed instead, the only harm would have been that the student would have had to learn a new language before he communicated with the greatest mathematicians; as it is, many will have to form a new language out of the materials of the old one, which is a much harder task. This injudicious innovation is now extinct.

5. Analogies should not be destroyed, unless false: for true analogy has been frequently the parent of discovery, and always of clearness. Thus the real analogy of $\Sigma\phi x\Delta x$ and $\int\phi x dx$ was lost to the eye by the use of $\int_x \phi x$ to signify the latter; an innovation which preceded the one last-mentioned, and has obtained more approbation in this country, though now almost extinct. The notation used by Fourier to express a definite integral, $\int_a^b \phi x dx$, will certainly prevent the spread of the one just alluded to; though this last itself is chargeable with breach of analogy: for $\int^2 \phi x dx^2$, $\int^3 \phi x dx^3$, &c., ought to represent the successive integrals of $\int \phi x dx$. Fortunately, however, the symbols $(\int dx)^2\phi x$ $(\int dx)^3\phi x$, &c., may represent these successive integrals; and thus the two notations may be combined. For instance, $(\int_0^x dx)^4\phi x$ represents the fourth integral of ϕx, each integration being made from 0 to x.

6. False analogies should never be introduced; and, above all, the incorrect analogies which custom and idiom produce in language should not be perpetuated in notation. It is becoming rather common to make editions of Euclid which are called *symbolical*, and which supply signs in the place of many words. To this, if properly done, there cannot be any objection in point of correctness: nor can we take any serious exception to the use of □ AB to stand for the square on AB, to ‖ for parallel, < for angle, ⊥r for perpendicular, &c. But when we come to AB . BC for the rectangle on AB and BC, AB² for the square on AB, we feel the case to be entirely altered. These are already arithmetical symbols: it is bad enough that the word *square* should have both an arithmetical and a geometrical meaning, and causes plenty of confusion: a good notation, if it cannot help in avoiding this confusion, should at least not make it worse. At the same time, with regard to symbolic geometry, we feel some repugnance to introduce it into the elements, from observing that all the best writers seem to feel with one accord that pure reasoning is best expressed in words at length. If it be desirable that a student should be trained to drop reasoning, except as connecting process with process, and to think of process alone in the intervening time, it is also most requisite that he should have a corrective of certain bad habits which the greatest caution will hardly hinder from springing up while he is thus engaged. Arithmetic and algebra amply answer the first end; and geometry, in the manner of Euclid, is the correcting process. Will symbolic geometry do as well? We will not answer positively, but we must say we much doubt it.

7. Notation may be modified for mere work in a manner which cannot be admitted in the expression of results which are to be reflected upon. The mathematical inquirer must learn to substitute, for his own private and momentary use, abbreviations which could not be tolerated in the final expression of results. Work may sometimes be made much shorter, and the tendency to error materially diminished, by attention to this suggestion.

For example, the complexity of the symbols,

$$\frac{dz}{dx}, \frac{dz}{dy}, \frac{d^2z}{dx^2}, \frac{d^2z}{dx\,dy}, \frac{d^2z}{dy^2},$$

greatly impedes the operations connected with problems in solid geometry: the letters p, q, r, s, t, which are often substituted for them, make us lose sight of the connection which exists between the meanings. But the symbols

$$z_x,\ z_y,\ z_{xx},\ z_{xy},\ z_{yy},$$

are not long nor complicated enough to partake much of the disadvantage of the complete symbols, while they are entirely free from that of the isolated letters.

8. In preparing mathematical writings for the press, some attention should be paid to the saving of room. In formulæ which stand out from the text, this is not of so much consequence; but in the text itself a great deal of space is often unnecessarily lost. For example, it is indispensable in formulæ to write a fraction, such as $\frac{a}{b}$, in the manner in which it here appears; but if this be done in the text, a line is lost; and, generally speaking, $a : b$, or $a \div b$, would do as well in mere explanation. Also, in printing, redundancies which are tolerated in writing, should be avoided, such as $\sqrt{7}$, where $\surd 7$ would do as well.

9. Strange and unusual symbols should be avoided, unless there be necessity for a very unusual number of symbols. The use of *script* letters, such as $\mathscr{A}$, $\mathscr{B}$, &c., or old English letters, as 𝔄, 𝔅, 𝔞, 𝔟, &c., except in very peculiar circumstances, is barbarous. A little attention to the development of the resources of established notation will prevent the necessity of having recourse to such alphabets. Nor is it wise to adopt those distinctions in print which are not easily copied in writing, or which it is then difficult to preserve: such as the use of A and *A*, &c., in different senses; even the distinction of Roman and Italic small letters, a and *a*, &c., should be sparingly introduced.

10. Among the worst of barbarisms is that of introducing symbols which are quite new in mathematical but perfectly understood in common language. Writers have borrowed from the Germans the abbreviation $n\,!$ to signify $1 \,.\, 2 \,.\, 3 \ldots (n-1)n$, which gives their pages the appearance of expressing surprise and admiration that 2, 3, 4, &c., should be found in mathematical results.

The subject of mathematical printing has never been methodically treated, and many details are left to the compositor which should be attended to by the mathematician. Until some mathematician shall turn printer, or some printer mathematician, it is hardly to be hoped that this subject will be properly treated.

The elements of mathematical notation are as follows:—

1. The capitals of the Roman alphabet, and the small letters of the Italic. The small Roman letters and the Italic capitals are rarely used, and should be kept in reserve for rare occasions.

2. The small letters of the Greek alphabet and such capitals as are distinguishable from the corresponding Roman ones, as Δ, Φ, Ψ.

3. The Arabic numerals, and occasionally the Roman ones.

Of all these there should be three different sizes in a good mathematical press, and the different sorts should bear a much better proportion to one another than is usual. The Greek letters seldom set properly with the Roman ones, and few indeed are the instances in which such symbols as

$$a^{m^n} \qquad \epsilon^{(1+t)^2}$$

are, as they ought to be, good copies of the manner in which they are written. The handwriting of a bad writer is frequently more intelligible to the mathematical eye than the product of the press. Among the faults to which the compositor is naturally subject, and which frequently remain uncorrected by the author, is that of placing blanks or spaces in the manner in which he would do in ordinary matter, by which he is allowed to separate symbols which are in such close connection that absolute junction would not be undesirable. For instance, $\cos\ \theta$ for $\cos\theta$, $(a\ b+c\ d)$ for $(ab+cd)$. As a general rule, the manuscript should be imitated.

4. Accents, superfixed and suffixed, as in a'', $a_{\prime\prime}$. These are generally continued, when they become too numerous, by Roman numerals, as in $a_{\prime}$, $a_{\prime\prime}$, $a_{\prime\prime\prime}$, a_{iv}, a_{v}, a_{vi}, &c.

5. The signs $+ - \times \div : \surd$, and the line which separates the numerator from the denominator. Of these there are generally not sizes enough, particularly as to the sign $-$. It frequently happens that such an expression as $(x-1)\ (x-2)\ (x-3)$ &c. overruns a line very inconveniently, when the use of a shorter negative sign, as in $(x{-}1)$ $(x{-}2)$ $x{-}3)$ would avoid such a circumstance altogether. Between the division line of a fraction and the numerator and denominator unsightly spaces very often occur, as in

$$\frac{a+b}{\;c+d\;} \text{ instead of } \frac{a+b}{c+d}.$$

6. The integral sign $\int$. with its limits expressed, as in $\int_a^b$: the symbols of nothing and infinity, 0 and ∞.

7. Brackets, parentheses, &c. [ ], ( ), { }, &c. These are often not properly accommodated to the size of the intervening expressions, particularly in thickness.

8. The signs of equality, &c., $=$, $<$, $>$.

9. Occasionally, but rarely, a bar or a dot is used over a letter, as $\bar{a}$ or $\dot{a}$. In some works, accents and letters are placed on the left of a symbol, as in ${}'a$, ${}^2a$, ${}_2a$. This however should be avoided, as it is difficult to tell to which letter the symbol belongs; and there are ample means of expression in what has been already described.

There are no general rules laid down for the use of notation: a few hints however may be collected from the practice of the best writers of recent times.

1. When a letter is to be often used, it should be, if possible, a

small letter, not a capital. The latter species is generally used for functions of small letters.

2. The letters d, Δ, δ, and D, are appropriated for operations of the differential calculus, and should hardly ever be used in any other sense.

3. When co-ordinates are used, the letters x, y, z, must be reserved to signify them; x, y, z, and ξ, η, ζ may be used if different species be required, and if x', y', z', &c., or $x_{,}, y_{,}, z_{,}$ &c., should not be judged convenient.

4. When functional symbols are wanted, the letters ϕ, ψ, χ, F, f, Φ, Ψ, should be first reserved for them; afterwards π, ϖ, τ, sometimes π, ξ, μ, ν.

5. The letter π is, by universal consent, appropriated to 3·14159 . . . , and ϵ (by the French e) to 2·71828 . . . . ; Γ to the functional symbol for 1 .2.3. n.

6. When many operations of differentiation occur, superfixed accents should be avoided in any other sense than that of differentiation.

7. When exponents are wanted to aid in signifying operations, the powers should be carefully distinguished. Thus, in a process in which $\sin^{-1}x$ is very much used for the angle whose sine is x, the square cube, &c., of $\sin x$ should not be $\sin^2 x$, $\sin^3 x$, &c., but $(\sin x)^2$, $(\sin x)^3$, &c. Some writers would have the latter notation employed in all cases; but this is, we think, asking a little too much.

8. Greek letters are generally used for angles, and Italic letters for lines, in geometry. To this rule it is desirable to adhere as far as possible, but it cannot be made universal.

9. Suffixed numerals are generally the particular values of some function. Thus a_v means a function of v, of which the values for $v=0$, $v=1$, &c. are a_0, a_1, &c.

10. As to the radical sign, $\sqrt{a}$, $\sqrt[3]{a}$, &c., do not generally mean any one of the square roots, cube roots, &c., of a, but the simple arithmetical root. The indeterminate root is usually denoted by the exponent. Thus $a \pm \sqrt{b}$ may be necessary, but $a \pm b^{\frac{1}{2}}$ has a superfluity.

11. The same letters should be used, so far as possible, in the same sense throughout any one work; and some preceding good writer should be followed. As a general rule, those only are entitled to invent new symbols who cannot express the results of their own investigations without them.

The writer who is most universally acknowledged to be a good guide in the matter of notation is Lagrange. This subject is of great importance; but fortunately it is pretty certain that no really bad symbol, or system of symbols, can permanently prevail. Mathematical language, as already observed, is, and always has been, in a state of gentle fermentation, which throws up and rejects all that cannot assimilate with the rest. A received system may check, but cannot ultimately hinder, discovery: the latter, when it comes, points out from what symbolic error it was so long in arriving, and suggests the proper remedy.

For the progress of mathematical language, see MATHEMATICS, RECENT TERMINOLOGY IN; and TRANSCENDENTAL: see also SYMMETRY.

SYMMETRY, SYMMETRICAL (Mathematics). These terms are now applied to order and regularity of any kind, but this is not their mathematical meaning. Euclid first used the word "summetros" (σύμμετρος) to signify *commensurable*, and this well-known Latin word is in fact merely the literal translation of the Greek: two magnitudes then were symmetrical which admitted of a common measure. In later times, and those comparatively recent, the word was adopted both in geometry and algebra in different senses.

Since symmetrical applies in its etymology to two magnitudes which can be measured together (by the same magnitude), the term would, as to space-magnitudes, naturally apply to those which may be made to coincide. But the term *equal* had occupied this ground; and when, in Euclid, the word equal, which was originally defined in the manner just expressed, had degenerated into signifying equality of area only, the term SIMILAR entered to express sameness of form, so that figures having perfect capability of coincidence, or the same both in size and form, were called equal and similar. The word symmetrical was therefore not wanted, and was finally introduced to signify that obvious relation of equal and similar figures which refers to their position merely, and consists in their corresponding portions being similarly placed on *different sides* of the same straight line; so that coincidence cannot be procured without turning one figure round that straight line. Suppose, for instance, the front of a building to be *symmetrical*: draw a vertical line through the middle of the elevation, and the two lateral portions are equal and similar, as Euclid uses those words. But they are more than equal and similar; they are symmetrical: the right-hand side stands in the right-hand portion of space, with respect to the dividing line, and in exactly the same manner as the left-hand side stands in the left-hand portion of space. If the architect were to preserve equality and similarity, without symmetry, he would make two left sides, or two right sides, to his building, but not one right and one left. In the letter W there is a want of symmetry, but not in O: to make W symmetrical, both the inner lines should be thin, and both the outer ones thick.

Euclid assumes the power of turning a plane round, so as to apply the faces of two figures to one another, in such manner that, after the application, the spectator must be supposed to see through the paper or other imaginary substance of which his plane is the surface. He has then no occasion to consider symmetry; that is, figures being equal and similar, no cases can arise in which it makes any difference of demonstration whether they be symmetrical or not. When he comes to solid figures, he assumes a postulate in the garb of a definition, which dispenses him from the consideration of symmetry; namely, that solid figures consisting of the same number of equal planes, similarly placed, are equal. He seems to imagine that such solids must evidently be capable of being made to occupy the same space, which, though true as to quantity of space, is not true as to its disposition. Two solids may be equal in every respect, and yet it may be impossible (and precisely on account of their symmetry) to make one occupy the space previously occupied by the other. The two hands furnish an instance: they give the idea of equality (of size), similarity (of form), and symmetry (of disposition). Yet they cannot be made to occupy the same space, so as, for instance, to fit exactly the same glove; and a sculptor who should cast both hands from the same mould, would be detected immediately as having given his figure two right hands or two left hands. Again, suppose two solids, irregular pyramids for instance, composed of planes similar and equal, each of one to one of the other. Let coincidence be attempted geometrically: the two bases must of course be made to coincide. If, then, the two vertices fall on the same side of the common base, the figures will coincide altogether; but if the two vertices fall on opposite sides of the bases, absolute coincidence is impossible. Legendre proposed to call such solids by the name of *symmetrical*, in doing which he introduced the term of common life in an appropriate manner.

In algebra, a function is said to be symmetrical with respect to any two letters when it would undergo no change if these letters were interchanged, or if each were made to take the place of the other. Thus,

$$x^3 + a^2x + ab + b^2x$$

is symmetrical with respect to a and b; interchange would give

$$x^2 + b^2x + ba + a^2x,$$

the same as before. But this expression is not symmetrical with respect to a and x, for interchange would here give

$$a^2 + x^2a + xb + b^2a.$$

An expression is symmetrical with respect to any number of letters when any two of them whatsoever may be interchanged without alteration of the function. Thus $a^2b + ab^2 + a^2c + ac^2 + b^2c + bc^2$ is symmetrical with respect to a, b, and c. It is not sufficient that certain contemporaneous changes should be practicable without producing alteration: *any two* must be interchangeable, the rest remaining. Thus $a^2b + b^2c + c^2a$ is unaltered if a become b, b become c, and c become a, at the same time, but it is not symmetrical; for if a and b only be interchanged, it becomes $b^2a + a^2c + c^2b$, or is altered.

Attention to *symmetry* is of the utmost consequence in mathematical notation. Here the word means that quantities which in any manner have a common relation should have something common in the symbols of notation; and analogy is perhaps a better word than symmetry. Suppose, for instance, we had taken, for the equation of a SURFACE OF THE SECOND DEGREE, $ax^2 + by^2 + cz^2 + dxy + exz + fyz + gx + hy + kz + l = 0$. Our formulæ would have been confused masses of letters, no set of which would have presented any similarity, or have easily remained in the memory. But in the article cited there is no set of formulæ of which more than one need be remembered; the others must be suggested by it.

SYMMETRY, CENTRE OF. [CENTRE, col. 734.]

SYMPATHETIC INK. [COBALT.]

SYMPHONY (σύν, *with*, and φωνή, *sound*), a term very differently understood at different periods of musical history. Some writers, according to Zarlino (Parte 3za, cap. lxxix.), have considered it as an instrument of the lyre kind. Others have thought it a sort of drum. If an instrument, that it was used as an accompaniment—most probably to the voice—the word in its original signification leads us naturally to conjecture.

With the moderns, Symphony, or *Sinfonia*, signifies a musical composition for a full band of instruments, and, up to the latter part of the last century, the word was synonymous with overture; symphonies, and among these several of Haydn's early ones, having been called overtures. Even at the present day the overture in the composer's score of an Italian opera is usually termed *Sinfonia*. The modern symphony generally consists of four movements: a brilliant allegro, which is commonly preceded by a slow introduction; an expressive adagio or andante; a minuet with its trio; and a finale. Instead of the minuet, what is called a *Scherzo*, a short, animated, sportive movement, is sometimes substituted. But composers are not restricted by any rule regarding the number of movements. Mozart's second symphony in D has but three, besides the slow introduction; while Beethoven's Pastoral and Choral symphonies may be said to comprise six or more.

Symphony is a term also applied to the instrumental introductions, terminations, &c., of vocal compositions; and these are sometimes called ritornels, from the French *ritournelle*, or the Italian *ritornello*.

SYMPIESOMETER. [BAROMETER.]

SYMPTOM (συμπτωμα, an incident, or coincidence) is any change in the appearance or functions of the body differen from those which occur in health, and perceptible to the senses either of the patient or his physician. Symptoms must not be confounded with signs of disease. The observation of facts by means of our senses renders us acquainted with symptoms, but it is by medical reasoning thereupon that we deduce signs. A patient often knows his own symptoms, but is nevertheless ignorant of the disease under which he labours.

The signs of disease are inferences drawn by the mind from the observation of symptoms. The most striking symptoms often furnish only accessory signs, while the most obscure are the signs characteristic of the disease. Violent pain in the head not unfrequently attends inflammation of the lungs, but is a symptom of very small importance, while slight pain in the side, or a streak of blood in the expectoration, furnishes a very valuable sign, and helps to disclose the nature of the affection.

Symptoms are best divided into the *essential*, which are peculiar to certain diseases, the *accidental*, produced by some circumstance of unusual occurrence, and the *common*, which are met with alike in various complaints.

That part of medicine which treats of symptoms is called Symptomatology: Semeiology is the name applied to the investigation of the signs of disease, and of their comparative value.

SYNAGOGUE (*Συναγωγή*), a word which primarily signifies any assembly or congregation, but came to be applied, among the Jews, to places where any assemblies, especially those for the worship of God, met, or were convened. In the later Hebrew, such places were called בֵּית כְּנֶסֶת, "house of assembly." There is no trace of synagogues among the Israelites prior to the Babylonish captivity, nor, in express terms, until a long time after. It is collected, however, that the origin of such establishments may be referred to that period. Being then debarred from their customary religious observances, they were accustomed to assemble on the Sabbath-day, to hear portions of the law read and expounded; and those who ultimately returned from exile kept up this custom in Palestine. (Nehem. viii. 18.) These assemblies or meetings became in due time fixed to certain places, and a regular order was observed in them. They existed considerably earlier among the Jews settled in foreign parts than in their own country, where we do not find them until the time of the Asmonæan princes; but after their introduction they increased rapidly. The synagogues appear to have been originally erected outside the towns, in the fields, usually near waters, for the benefit of ablution; but they were soon introduced into the towns, and were usually on the most elevated spots. In large towns there were several, and the Jewish writers affirm that there were 480 in Jerusalem. The assemblages were at first confined to the Sabbath-days and festivals, but were latterly extended to the second and fifth days of the week (Mondays and Thursdays). The services consisted chiefly in prayer, and in the reading and exposition of the sacred books. At first the readings were confined to the law, but were at length made to comprehend portions of the prophets, psalms, and other books. The whole concluded with a prayer and benediction, to which the congregation responded "Amen."

It seems to have been the custom for a synagogue not to be opened in any place where ten men could not be found of sufficient leisure to attend to its affairs. Where no separate building existed, a room in some private house was the place of meeting. There are no ancient indications that the synagogues had any peculiar form; but each of them had a kind of altar or table, at which the volume of the law was read; and at the east end was an ark or chest in which that volume was kept. The seats were so disposed that the face of the people was turned towards this sacred repository and towards the elders, who alone sat with their backs to the ark, and their faces to the people. The synagogues were used not only for worship, but for holding local courts of justice, which had cognisance of petty offences requiring no higher punishment than stripes, which were inflicted on the spot. (Matt. x. 17; Luke, xii. 11; Acts, xxii. 19.) The affairs of the synagogue were under the direction of several officers: the chief of them was the archisynagogus (*ἀρχισυναγωγός*), or "ruler of the synagogue," who regulated its affairs, and without whose leave no one could read or preach. (Mark, v. 22; Luke, xiii. 14.) Next to him was the officer called שְׁלִיחַ צִבּוּר "Sheliach tsibbor," or "angel (messenger) of the church," who prayed in behalf of the congregation. The חַזָּן "Chazan," who is the reader in modern synagogues, appears to have been the "minister" (Luke, iv. 20) who had charge of the sacred books. As it appears from Acts, xiii. 15, that there were several archisynagogi, it is probable that they answered to the committee of elders, by whom the synagogues are at the present time managed.

With some necessary modifications, the ancient usages are still maintained in the modern synagogues. The highest ground that can be conveniently appropriated is still chosen for the site of a synagogue. In this part of the world it extends east and west, with the entrance, or principal entrance, in the west, that as the people enter, and as they sit, their faces may be turned towards the land of Canaan. The altar or desk is on a raised platform surrounded by a wooden rail, and large enough to contain several persons: the women do not mingle with the men, but have a separate part or gallery (if there be one), where a wooden lattice screens them from observation. The men keep their heads covered in the synagogues.

The first synagogue in England of which we have historical knowledge is that which, in the reign of William Rufus, existed at Oxford, where the Jews were then numerous; but it is likely that they had one then or before in London also, as the fact that their only burial-place in England was on the spot now called Jewin Street, indicates that this was their principal seat. In the reign of Henry III. they lost a synagogue, which they had erected in the Old Jewry, on the complaint of the Friars Penitent in the neighbourhood, that they could not consecrate the elements in quiet on account of their "howlings. So late as the reign of George II. the only synagogues allowed in England were the two in London, one for the Portuguese Jews in Bevis Marks, and the other for the German Jews, in Duke's Place There is now no restriction; they have several synagogues in London and at least one in most of the principal towns, and the total number in England was fifty-three in 1860.

SYNAPTASE. [Ferment.]

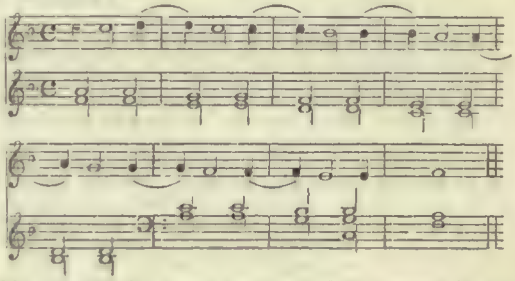
SYNCELLUS (*σύγκελλος*), a Greek word, equivalent to *concellaneus* in Latin, and meaning a person who inhabits the same chamber (*cella*) with another, was used by the Christians of the early and middle ages as the name of an ecclesiastical dignity. The Syncellus was constantly with the patriarch, metropolitan, or bishop, as an inspector of his life and manners. The successors to the patriarchs and metropolitans were very often chosen from the Syncelli. Their rank was very high, and at one time they even claimed precedence over the metropolitans. Their number was considerable, till by a constitution of Heraclius the greatest number allowed in one church was two.

The chief of the Syncelli was called Protosyncellus (*πρωτοσύγκελλος*), and the president of their assemblies was called *πρωτοπρόεδρος τῶν πρωτοσυγκέλλων*.

The suffragan bishops [Bishop] were also called Syncelli.

(Du Cange, *Glossar. Med. et Inf. Latin.*, s. v. 'Syncellus.')

SYNCOPATION, in Music, is when the first half of a note begins on the unaccented or weak part of a bar, and the other half is continued and terminates on the accented or strong part. [Accent, *in Music.*] Example:—



In this example the upper part, or melody, consists in fact of a succession of syncopating minims; but the bar dividing the alternate ones, they can only be written as two crotchets bound together: though formerly the bar was, in most cases, made to cut the note in two. Example:—

Syncopated notes are, by some writers, termed *driving notes.*

SYNCOPE (*συγκοπή*, literally a cutting in pieces, a sudden failure of power or strength), fainting. A sudden impairment or complete loss of sensation and voluntary motion, with great diminution or almost total abolition of the heart's action and of the function of respiration.

Fainting sometimes occurs quite suddenly, but is usually ushered in by certain premonitory symptoms. These are a sense of languor and uneasiness, confusion of the mind, oppression at the chest, dimness of sight, ringing in the ears, partial cold sweats, paleness of the face, and coldness of the extremities. These continue for some time, and then either pass away, or are followed by swooning, a state of complete faintness, during which the pulse is altogether imperceptible at the wrist, and respiration nearly ceases. When a fainting fit comes on suddenly and without any warning, it is usually more profound than when it has been preceded by the symptoms just enumerated. Recovery from fainting is frequently attended with palpitation of the heart, and sensations more distressing than those which ushered in the attack. The duration of a fainting fit seldom exceeds a few minutes or even seconds, but instances are on record of persons continuing in a swoon for many hours.

The immediate cause of fainting is, in all instances, some interruption to the due transmission of blood to the brain. Various circumstances however, both moral and physical, interfere with the circulation, either through the medium of the nervous system, or by acting directly on the heart itself. Persons swoon from any violent and sudden moral emotion, as terror, grief, disappointment, or even excessive joy. The sight of blood or of any object which excites disgust occasions some persons to faint, as do various impressions on the senses, whether painful or otherwise. Very susceptible individuals have been known to faint on perceiving the odour of certain flowers, and unpleasant smells still more frequently cause faintness. The abstraction of a large quantity of blood probably has a more immediate action on the heart; and to the disturbance of the circulation must be attributed those fainting fits which sometimes occur in the course of diseases of the heart. The sudden transition from a horizontal to a sitting posture when persons are very weak, or have lost a large quantity of blood, probably acts in both ways at once; and fainting sometimes takes place from other causes, such as heated rooms, &c., of which we cannot well explain the action.

Fainting may be confounded with apoplexy or asphyxia; and if it continues for an unusually long time, the person may be supposed to be dead. A little attention however will prevent our mistaking an apoplectic person, who breathes loudly and with a snoring noise, for a person in a swoon, whose respiration is gentle, and almost imperceptible, and whose pulse either cannot be felt at all, or is at any rate extremely weak. Asphyxia is a state of suspended animation, brought on by some cause interfering directly with respiration; it is marked by tumor and lividity of the face, while the face of a person in a fainting fit is pale and sunken. The continuance of respiration and of the heart's action, though very feeble, the temperature of the body, and the absence of all stiffness of the limbs, would sufficiently distinguish syncope from death; but it must be very unusual for fainting to continue for a few minutes without there appearing some evident signs of life. [ASPHYXIA.]

In the treatment of a person who has fainted, the first point is to place him in the recumbent posture; and in the case of fainting after blood-letting, nothing more is in general required. Exposure to the cool air, sprinkling cold water on the face, and friction of the limbs may be employed if the fit continues; and a small quantity of ether or sal-volatile may be given as soon as the person can swallow. The horizontal posture should be preserved until recovery is complete.

SYNDIC comes from the Greek "syndicos" (σύνδικος). The Greek word Syndicos originally signified one who aided another in a matter before a court of justice, and hence it came to signify generally an advocate, one who maintained another's cause before a court of justice. Syndicos also signified at Athens one who was appointed by the state to attend to its interests in any matter in dispute between Athens and another state: thus Æschines was elected their Syndicos by the Athenians in a matter relating to the temple at Delos. (Demosthen. Περὶ Στεφάνου, c. 42.) There were also functionaries at Athens called Syndici, who were appointed, after the establishment of the tyranny of the Thirty, to decide on cases of confiscated property. The word Syndicus passed into the Latin language. It often occurs in the 'Digest' in the sense of an attorney or agent for a university or corporate body: in this sense it is used as synonymous with Actor by Gaius. ('Dig.' 3, tit. 4, s. 1.) In the middle ages also the word Syndicus was in common use, and was frequently given to the agent or factor appointed by corporate bodies to manage their common affairs, and especially to represent them in courts of law. Crevier, in various places, designates the syndic of the university, or of the faculty of arts, by the equivalent names of procureur, agent, greffier (iii. 230; iv. 309; v. 459). In the same sense most of the other corporate bodies in Paris and other French towns used to have their syndics; and the syndic was also the usual name for the solicitor to the community, or town-clerk, in the towns of Languedoc and Provence. The clergy, in like manner, had their Syndics Généraux, Syndics Diocésains, and Syndics Provinciaux; and Syndics, or agents resident at Paris, were also appointed by most of the religious orders. The functions of the different syndics however varied considerably; some were mere agents or solicitors, others were representatives of their corporations in a higher sense, sometimes acting as their presidents, and deciding causes, instead of merely conducting them. The four chief magistrates of the city of Geneva used to be called Syndics. Among the Burdegalenses (or people of the district of which Bordeaux is the capital), the office of Syndic, supposed to have meant originally the defender of a military post, became in course of time an hereditary title of nobility; of which several instances occur in Froissart, and other chroniclers of the 14th century. In more recent times, when Louis XIV., in 1701, directed the establishment of chambers of commerce in the principal towns of France, the merchants and other persons composing them were appointed to be called Syndics du Commerce, or Syndics de la Chambre de Commerce. For the significations of the various old words derived from or connected with Syndicus, the reader is referred to Ducange, 'Gloss. M. et I. L.,' vi. 928-931; and 'Supplem.,' iii. 932. We shall merely mention that the French have the verb "syndiquer," for to judge or censure, as we formerly said "to syndicate" in the same sense.

SYNOCHUS and SYNOCHA, forms of fever recognised by most of the older and many recent writers on the practice of medicine. Sauvages defined Synochus to be a fever which lasted more than a fortnight without materially weakening the pulse; whilst Cullen used this term to express a fever which combined the two forms of inflammatory and putrid fever, that is, a fever which at its commencement was inflammatory and at its close putrid. The inflammatory form of fever which was characterised by running its course rapidly, and marked by high excitement of the heart and arteries, was called Synocha by Cullen. A putrid and low form of fever was called Typhus. The latter term is now, however, applied to all continued contagious fevers, and the former terms are not often used at all. [FEVER, CONTINUED.]

SYNOD, a Greek word, Σύνοδος (literally, "a coming together"), adopted by the Saxons, sometimes used for an assembly of any kind, but much more commonly for an assembly gathered for ecclesiastical purposes, and more particularly for an assembly of bishops or presbyters deputed by various churches or branches of the universal church to meet at an appointed place, there to deliberate on points of doctrine or other matters relating to the regulation and welfare of the church. These synods are also called councils. Of these the highest are called œcumenical, by which is meant representative of all the different branches of the church established throughout the habitable world (οἰκουμένη). [ŒCUMENICAL COUNCILS.]

Very few synods or councils have been held in the Protestant churches. By far the most remarkable is that of Dordrecht or Dort, which was assembled in the reign of our king James I. Its professed object was to compose the differences existing between the Calvinian and Arminian parties in the Protestant church. The former prevailed.

The doctrine of the Church of England respecting councils may be seen in the Twenty-first Article.

Lists, very full and perhaps complete, of the several councils which have been held, may be found in many treatises on chronology, particularly the 'Tablettes Chronologiques,' of M. Dufresnoy; and in 'L'Art de Vérifier les Dates.'

SYNODIC, SYNODIC REVOLUTION (σύνοδος, conjunction of paths). The synodic revolution of two bodies which move round a common centre is that portion of one or more actual revolutions in which they go through all their possible relative positions. The simplest instance which can be given is that of the two hands of a watch: the absolute revolution of the minute hand is made in one hour, that of the hour hand in twelve hours; but the synodic revolution of the two hands is the interval which elapses between any time at which they are together, and the next time at which the same thing takes place.

Every phenomenon which depends upon the relative position of two revolving bodies cannot complete all its phases in less than a synodic revolution. Thus, in the case of the sun and moon, the total disappearance of the latter which takes place when they are nearest in the heavens, cannot take place again until they are again at their nearest, that is, until the moon has not only completed the circuit of the heavens, but has further progressed until she overtakes the sun. The actual revolution of the moon is not an object of interest, except to those who watch her progress among the fixed stars: the phases which are visible to all the world depend solely on her motion relatively to that of the sun. Those who would make a common watch tell time in a manner resembling the indications of luni-solar phenomena must rub out the marks of minutes and hours from the dial-plate, and choose for an interval of measurement that which elapses between successive conjunctions of the minute and hour hands.

If the two revolutions be made in the same direction, and if T and t be their respective times, T being the greater, the time of the synodic revolution is

$$\frac{Tt}{T-t}.$$

For, if x be the time of a synodic revolution, the portion of an actual revolution which the quicker has gained upon the slower is

$$\frac{x}{t}-\frac{x}{t};$$

but by hypothesis this is a whole revolution, since the synodic period is nothing but the time in which the quicker gains a whole revolution upon the slower. Equate the last formula to unity, and the resulting value of x is the first formula. But if the two revolutions be made in opposite directions, the synodic revolution is made in the time

$$\frac{Tt}{T+T}.$$

Thus in the case of the hands of a watch, $T=12^h$, $t=1^h$; and $\frac{12}{11}$ of an hour, or $1^h\ 5^m\ \frac{5}{11}$, is the interval of two conjunctions of the two hands.

To find roughly the synodic period of the sun and moon, let us take the sun's actual revolution at 365¼ days, and moon's at 27¼ days. We have then

$$\frac{365\frac{1}{4}\times 27\frac{1}{4}}{365\frac{1}{4}-27\frac{1}{4}}=29\tfrac{1}{2}\text{ days nearly.}$$

SYNONYME. The word synonyme is applied to different words, which mean, or are supposed to mean, the same thing: as valour, courage; virtue, goodness; vice, wickedness. Though words are often considered to be synonymous, it is probable that very few words in the same language really are synonymous. If we compare two languages, we may find synonymes; thus the words for man, horse, dog, &c., taken in any number of languages, may be considered synonymous. Words belonging to the same language may also be synonymous, where the language has received additions from various other languages, among which additions there may be terms which are synonymous (in the modern sense) with native terms of the language into which they are introduced. Thus in English there may be Saxon terms which are, or rather once were, synonymous with other terms which have been introduced into the English immediately from the Latin, or through the medium of the Italian and the French. It is said "once were," because though such words may have been synonymous originally, and introduced by writers for the sake of variety or harmony, or to avoid repetition of the same word, it rarely happens that such words continue to have their original meaning.

SYNTAX. [Language; Organon.]

SYNTHESIS. [Analysis.]

SYNTHESIS, CHEMICAL. The process of forming a chemical compound from its constituents; thus the production of phosphoric acid by the combustion of oxygen in air is a synthetical operation. The synthesis of inorganic substances is generally easily accomplished, but that of organic bodies is much more difficult. [Organic Compounds, *Artificial production of.*]

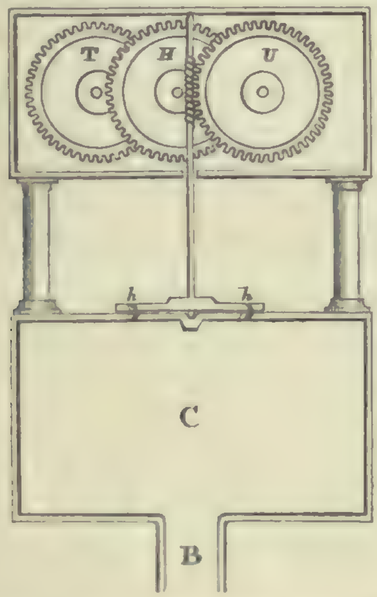
SYNTONIN. A name given by Mulder to the fibrin of the muscles.

SYPHON. [Siphon.]

SYPHON GAUGE. [Siphon Gauge.]

SYPHON, REVERSED. [Water Works.]

SYREN, an instrument invented by M. Cagniard de la Tour for determining the number of vibrations per second of any given note.



The fanciful name of the instrument was given from the fact that it is capable of exciting vibrations in water or any other fluid. It consists of a cylindrical chamber of brass C, about 3 inches in diameter, and 1½ inch high, connected with which is a tube B, which fits into the tube of a double pair of bellows. The upper surface of C contains a circle of holes, inclined somewhat obliquely, and coinciding with this circle is another circle of holes, inclined at an angle with the first, and contained in a disc of metal *h*, free to move on a vertical axis. This axis has near its upper extremity a perpetual screw which gives motion to a wheel U, of 100 teeth, and this acts on a hundreds wheel, marked H, and this again on a thousands wheel, marked T. Now suppose each circle of holes to contain 25. On sending a blast of air through B, it will, in escaping through the holes in C, cause the disc *h* to rotate with a speed depending on the force of the blast, and during each turn of the disc the currents will be cut off and re-opened 25 times, producing in fact, 25 waves of sound. One hole in each disc would produce, with a given velocity, the same note as 25, but the larger number produces a louder tone. By regulating the force of the blast, the disc may be made to vary in speed, so as to produce notes from the gravest to the most acute. By making the syren give the note, the velocity of whose vibrations we wish to determine (that of a tuning fork for example), the total number of rotations of the disc, as recorded by the dials attached to the wheels U, H, T, divided by the number of seconds during which the observation is being made, will give the number of vibrations per second for the note in question. By a simple adjustment, the endless screw can be put in and out of gear with the teeth of the wheels in a moment, so that the registration need not begin until the instrument is sounding the note fully and freely. A seconds pendulum should also be at hand, beating audibly, so that the observer may begin to count the moment the screw is put in gear. Some practice is required to make the instrument sustain the note for 8 or 10 seconds. Graduated dial-plates and moving hands, as in a gas-meter, are connected with the wheels U, H, T, so that the number of vibrations can be read off by simple inspection.

SYRIAC LANGUAGE. [Aramæan Language; Language.]

SYRIAC VERSIONS of the Bible. Of these several exist, two of which are of considerable importance. 1. "The Peshito (*literal*) Version," also called "The Old Syriac Version," is one of the most ancient and valuable translations of the Bible. The date of its execution is unknown; but it is certainly of a high antiquity. It is referred to by Ephrem the Syrian, in the middle of the 4th century, as generally known and used, and therefore it must have been in existence a considerable time before. Modern critics have referred its date variously to the 1st, 2nd, and 3rd centuries, the majority to the 1st. The opinion now generally adopted is that of Michaelis, who ascribes the translation of both Testaments to the most flourishing period of the Syrian Churches, namely, the end of the 1st and the beginning of the 2nd century.

The version of the Old Testament was certainly made from the Hebrew, which it closely follows; but there are indications of the translator having made use of the Septuagint and of the Chaldee paraphrase. The great antiquity of this version, much higher than that of any existing Hebrew manuscript of the Old Testament, makes it a most valuable source of biblical criticism. It is on the whole a very good translation, but not equal throughout. A different method of interpretation is followed in different books, for instance in the Pentateuch and the Chronicles. From this circumstance Jahn infers that it was the work of different persons. Several peculiarities tend to prove that the translators were Christians, and probably converted Hebrews.

The version of the New Testament contains the four Gospels, the Acts of the Apostles, the Epistles of Paul (including that to the Hebrews), the First Epistle of John, the First Epistle of Peter, and the Epistle of James. It is undoubtedly one of the best versions of the New Testament in any language, and is used as their standard by the churches of Syria and the East.

The version of the Old Testament was first printed in the Paris Polyglott, but from an imperfect manuscript; the passages which were wanting were indifferently translated by Gabriel Sionita from the Vulgate. This text, revised by the help of four manuscripts, was reprinted in Walton's Polyglott, but was on the whole carelessly done. The best version is that of the Rev. C. Buchanan and Professor Lee, published by the British and Foreign Bible Society in 1816, which has been translated by the Rev. James Murdock, and was published in New York in 1851. The version of the New Testament was first brought into Europe by Moses of Mardin, who was sent by Ignatius, the patriarch of Antioch, on a mission to Pope Julius III. in 1552. It was first printed at Vienna in 1555, at the expense of the emperor Ferdinand I.

There is a later and very inferior translation of the books of the New Testament which are wanting in the Peshito, namely, the second Epistle of Peter, the second and third of John, the Epistle of Jude, and the Apocalypse, made from the original Greek, probably in the 6th century.

2. The Philoxenian, or Syro-Philoxenian Version of the New Testament, is so called from Philoxenus, bishop of Hierapolis, in the province of Aleppo (488-518), under whose auspices it was translated by Polycarp. It was revised by Thomas of Heraclea in 616. It is translated from the Greek text, but is very inferior to the Peshito.

In 1842 an imperfect copy of the four Gospels was brought by Archdeacon Tattam from the monastery of St. Mary Deipara in Syria, and is now in the library of the British Museum. It has been carefully edited, and translated by Dr. William Cureton, who considers its date to be of the 5th century. It differs from the Peshito, as well as from the Septuagint and the Greek in many passages, which are pointed out by Mr. Cureton in the printed edition published in 1858.

There are other Syriac Versions, not of sufficient importance to require a separate notice.

A list of the editions of the Syriac Versions is given in the 'Bibliographical Appendix' to the second volume of Horne's 'Introduction.'

SYRINGE (from Σύριγξ, a pipe), a portable hydraulic instrument of the pump kind, commonly employed for the forcible ejection of fluids. In its simplest form it consists of a cylindrical tube, with a perforated nozzle at one end, and a piston, to the rod of which a handle is attached. The tube being held in the left hand, with its nozzle immersed in water, the piston is drawn to the upper end of the tube by the right hand. The pressure of the atmosphere upon the surface of the water causes it to follow the piston, so that the syringe becomes filled with water. The instrument is then removed from the vessel of water, and, by pushing the piston back towards the nozzle, its contents may be ejected with a force proportionate to the power applied to the piston.

The use of syringes for extinguishing fires is alluded to under Fire-Engine. They were usually made of brass, and held from two to four quarts each. Those of the former capacity were about two feet and a half long, and one inch and a half in diameter, that of the nozzle being half an inch. They were furnished with handles on each side, and every syringe required three men to work it. The large syringes used for horticultural purposes might, in many cases, be used with advantage on the first discovery of a fire, when a very small quantity of water, promptly applied and accurately directed, might prevent serious mischief. Garden-syringes are made either to throw water in a compact jet, from a simple nozzle with one perforation, or to distribute it in the form of a shower, from a rose perforated with a number of small holes. In the latter case it is usual to add a nozzle of comparatively large bore, through which water is allowed to enter, although a self-acting valve prevents it from returning the same way. Several different caps may be fitted to the same syringe; those for throwing jets having the injection and ejection nozzles side by side, while those for producing showers have the injection nozzle in the centre of the rose. Syringes may also be applied with advantage in washing carriages, cleaning windows, and for other useful purposes. Mr. Baddeley has introduced many improvements in garden-syringes.

In medicine and surgery syringes of various kinds are employed in administering clysters; in injecting fluids into, or removing them from, the stomach or bladder; injecting liquids into wounds; and injecting coloured liquors or melted wax into veins, &c., in anatomical preparations. The application of the syringe as a stomach-pump is peculiarly important. In this case a flexible tube is put into the mouth of the patient, with a guard between the teeth to preserve it from injury, and a branch pipe is added to supply the syringe with liquid from a vessel, when it is used for injection, and to afford a channel for the escape of the abstracted liquid when the syringe is employed to empty the stomach. By an ingenious arrangement of valves, the same instrument may be so modified as to act equally well in either way. One method of using such an instrument is, first to inject a diluent into the stomach, and then to pump it back again, together with the injurious matter which it is desired to remove. Another plan is to inject a fluid into the stomach until an involuntary discharge takes place through the mouth, and to continue the operation until the stomach is cleansed, this being indicated by the fluid returning unchanged.

Mr. James Harris, of Plymouth, in 1822, devised a method of preserving oil-colours for painting in syringes formed of tin, or of brass tinned internally. A similar contrivance, in which the details differ from Mr. Harris's, although the same principle, that of propelling the piston by means of a screw, is preserved, has been brought into use; but tubes of very thin metal, from which the colour is expressed by collapsing the tube between the finger and thumb, without the use of a piston, have nearly superseded all other contrivances.

SYRINGE, CONDENSING AND EXHAUSTING. [AIR-PUMP.]

SYRINGIN. [LILACIN.]

SYRUPS are medicinal solutions of sugar, either in water alone, as in simple syrup, or in liquids charged with some peculiar principle of an active kind, such as senna or buckthorn, or merely grateful from its colour or fragrance, or both, such as syrup of violets. These must be of a proper consistence, either by having a suitable quantity of sugar added to the water at first, or by subsequent evaporation of the superfluous water. The former is the preferable mode, as the syrup keeps better. The purest and most thoroughly refined sugar should be employed, and generally in the proportion of two parts of sugar to one of fluid. Less sugar is needed where *acid* syrups are to be made, as in syrup of mulberries, and still less where *vinous* syrups are made. When made, the syrup is to be preserved in closely-stopped bottles, and kept in a cool place, the temperature of which never exceeds 55° Fahr.; but, with every precaution, fermentation is apt to occur, particularly if warm or boiling water has been employed to extract the vegetable principle, when cold water is most appropriate: so also with the syrup of poppies, which, when given in a state of fermentation to children, too often aggravates the disorder of the bowels it was intended to alleviate. To counteract the tendency to fermentation, rectified spirit is enjoined to be added to the sugar—an expensive proceeding, quite needless when cold water only is used in the preceding stages. When too little sugar is used, fermentation is still more apt to occur; when too much, the excess crystallises. Syrups are more used for their fragrance or colour than for their medicinal properties, which few possess to any important extent, except syrup of poppies, the cause of a larger mortality among children, especially of the poor, than any other drug: see Christison on 'Poisons,' and Reports of the Registrar-General, almost weekly, especially 17th Nov., 1860. The number of syrups might well be diminished.

SYSTEM (Astronomy). This term is applied to every theory of the disposition and internal arrangements of the solar system, or of the material creation generally. Thus we have the system of Ptolemy, of Copernicus, &c. Perhaps a short description of the distinctive characters of the different systems may be useful in a work of reference.

Ptolemaic.—The earth is an absolutely fixed centre, and the planets revolve in circles about centres which themselves revolve round the earth.

Copernican.—The sun is a centre, round which the planets revolve. Some of the machinery of the Ptolemaic system is retained.

Tychonic.—The sun is a centre of motion to all the planets, which revolve round it, while the sun and planetary orbits are carried together round the earth as a fixed centre.

Semi-Tychonic.—The sun is a centre of motion to Mercury and Venus, as in the Tychonic, and the motions of the other planets are as in the Ptolemaic system.

Newtonian.—There is no fixed centre, the sun only approximating to that character from its greater magnitude. The orbits of the planets are approximately represented by ellipses, exactly by ellipses of which the elements vary.

The Newtonian system is frequently called Copernican, from its rejecting what Copernicus rejected; but it is far from receiving all that Copernicus received. The introduction of the ellipse is due to Kepler. We have not included the system of Des Cartes [VORTICES], because it has reference to physical causes, and contains no peculiarity of arrangement. [PTOLEMAIC SYSTEM; BRAHE (TYCHO), COPERNICUS, and NEWTON, in BIOG. DIV.; PRINCIPIA; GRAVITATION; SOLAR SYSTEM, &c.]

The term system is also applied to the subdivisions of the solar system: thus we have the terrestrial, Jovial, Saturnian, Uranian systems.

SYSTEM (Mathematics), a word little used: we hear sometimes of a system of equations, or a system of curves or surfaces; the former meaning a set of equations which are related to each other in the same problem, the latter a class of curves or surfaces which are connected by any law.

SYSTEM, in the musical language of the Greeks, had the same signification as the word Scale has in modern music. [SCALE.] Each of the many genera of the ancients was a system in itself, if we may venture to assert anything positively concerning a subject which is involved in much obscurity. [GENERA.]

In modern music the term *System* is applied to any theory of harmony, that is to say, of the origin of chords, and of the manner of treating them in composition. Thus we have the systems of Rameau, Tartini, Kirnberger, &c. The system of Guido d'Arezzo, or that ascribed to him, included the elements of our present mode of notation; also the division of the scales into hexachords, and a mode of solmisation founded on such division. [GUIDO D'AREZZO, in BIOG. DIV; HEXACHORDS.]

SYZYGIES AND QUADRATURES. The syzygies of a planet or of the moon are those points of its orbit at which it is in conjunction or opposition with the sun: the quadratures are the precisely intermediate positions. Thus at new and full moon the moon is in syzygies; at half moon, in quadratures.

T

T is the thin (tenuis) letter of the dental or palato-dental series. For the various forms of the symbol by which it is represented, see Alphabet. The chief changes to which the letter is liable are as follows:—

T is interchangeable with *c*, as Lat. *nuc* (*nux*), Eng. *nut*. [See C (§ 6).] The resemblance of these letters in Latin manuscripts is so close, that it is often difficult to distinguish them. Hence there is much uncertainty in the orthography of many words in that language. Yet there is no doubt that *contio*, an abbreviation of *conventio* (*coventio*, in the sense of *contio*, actually occurs in the so-called bacchanalian inscription), and *nuntius* or *nountios*, an abbreviation of *novi-ven-tius* (compare *nov-i-tius*), should be preferred to the forms *concio*, *nuncius*, which are commonly found in English editions of Latin authors.

T interchangeable with *d*. [See D.]

T interchangeable with *th*, whether as pronounced in *thin* or in *the*. Thus the Latin *t* corresponds for the most part to *th* in English, as *tu*, *tres*, *tenuis*, *tundo*, *tum*, *trudo*, *torqueo*, *pater*, *mater*, of the former language, severally correspond to *thou*, *three*, *thin*, *thump*, *then*, *thrust*, *throw*, *father*, *mother*, of the latter. As regards the pair of words, *torqueo*, *throw*, it is worth observing that they both have a double meaning—*hurl* and *twist*. Even the termination of the third person in the Latin and old English verbs presents the same analogy, as *amat*, *loveth*.

T, or PT, interchangeable with *p*. [See P (§§ 7, 8).]

T interchangeable with *s*. [See S.]

T interchangeable with *l*. Thus the Latin words *lingua* (also *dingua*), *lacr-uma* (also *dacr-uma*), *lacerare*, *ligare* (also *dicare*), severally appear in English as *tongue*, *tear* (subst.), *tear* (verb), *tie*. *Mitis* of the Latin is allied to *mild* in English. Compare also the Latin *ali-quod*, &c., with the German *et-was*, &c. [See L.]

T interchanges with *nd*. This change is perhaps not common. Examples are—Lat. *et*, Germ. *und*, Eng. *and*; Lat. *sed* or *set*, Germ. *sond-ern*, Eng. *sund-er*, *sundry*, &c.; Lat. *fund-us*, Eng. *bottom*.

T interchangeable with *n*. Thus from the Icelandic perfect participle *haldin* we have a masc. nom. *haldinn* (for *haldins*), and a neuter nom. *haldit*; for it is an error to treat the *t* of this last form as a neuter suffix, seeing that neuters never differ from masculines except by curtailment. This change of *n* with *t* and *d*, accounts for the varied forms of our English participles, *holden*, *molten*, *melted*, *felt*, and the Scotch forms in *it*, as *abasit*.

T disappears from the beginning of words before *l*, as in *latus*, the so-called participle of *fero*, but in fact connected with the Latin *tollo*, and the Greek *τλη-μι*, *ταλ-ας*, *τολ-μη*. An older form of *latus* was perhaps *tlatus* or *stlatus*.

T in the middle of words, when flanked by vowels, often disappears. Thus the Latin words *pater*, *satis*, *vita*, *amatus*, *amata*, reappear in French as *père*, *sez* (in the compound *as-sez*, from *ad-satis*), *vie*, *aimé*, *aimée*. Similarly, from the map of Gallia, viewed in connection with the map of France, may be derived the examples, *Autura*, *Eure*; *Caturiges*, *Chorges*; *Catalauni*, *Châlons* (sur Marne).

T at the end of words is frequently dropped. Of the omission of a final *t* in pronunciation, the French language has numerous examples, as in *et*, *fait*, *est*, &c. It is very probable that a final *t* has in this way disappeared from the third person singular of many tenses in the French verb, as *il aime*, *il aimera*, *qu'il finisse*, &c. In the interrogative form *aime-t-il*, the interposed *t* really belongs to the verb, and owes its preservation in this form to the fact that a vowel follows. It is an error to attribute the insertion of the letter to the necessity of avoiding an hiatus. Even the Greek language drops this *t* in the suffix of the third person, as in *τυπτει*, *ετυπτε*, for *τυπτετι*, *ετυπτετε*. Compare the middle forms *τυπτεται*, *ετυπτετο*.

Ti before a vowel is often changed to a sibilant represented by *s*, *sh*, *ch*, &c. Thus from the Latin *faction* (*factio*) are derived the French *façon* and the English *fashion*. So *avaritia*, *malitia*, *vitium*, became in French and English, *avarice*, *malice*, *vice*.

TABERNACLE, THE (אֹהֶל מוֹעֵד, and sometimes, chiefly in *Numbers*, אֹהֶל הָעֵדוּת, or מִשְׁכַּן הָעֵדוּת; LXX., *σκηνή*, or *σκήνωμα τοῦ μαρτυρίου*; that is, the tabernacle of the testimony), was a sacred building, partaking of the nature of a tent, which was set up by the Israelites in the wilderness for the worship of God, and carried with them in their journeys. Hence it is called by Jewish writers "a portable temple" (*ἱερὸν φορητὸν*, Philo, 'Opp.,' ii., p. 146, *ναὸς μεταφερόμενος καὶ συμπερινοστῶν*: Joseph., 'Antiq.' iii., 6, 1). It was made under the direction of Moses, in exact conformity to a pattern shown to him by God when on Mount Sinai. (Exod. xxv. 40; xxvi. 30, &c.; Heb. viii. 5.)

Without doubt temples existed in Egypt, and possibly in Palestine, before the period of the exode; but the Israelites were not in a position to raise an edifice while on their migration to the promised land. They therefore were directed by Moses to construct a tabernacle. The description of it is sufficiently given in Exodus xxvi; but the translation of badgers' skins for the covering, xxv. 5, and xxvi. 14, is an unfortunate one, as the badger does not exist in south-western Asia, and would have been also an unclean animal, not likely to have been selected to have formed any part of the structure. The Hebrew word is tachash, used nowhere else except in Ezekiel xvi. 10, where it is stated to be used for the shoes of women. It has been conjectured that it implied the colour, in which sense the Septuagint and the Chaldee and Syria versions interpret it, though such interpretation has no support from the etymology, or in any of the kindred languages. There is little doubt that it means the skin of some animal. The seal has been suggested, but that is also a stranger to the region. Niebuhr and Ehrenburg believe it to have been the skin of a species of dolphin (the *Halicora Hemprichii*), which is perhaps the most likely, as the Arabs of the present day use the skin of that animal for their shoes or sandals.

Each of the sacred vessels and instruments had its appointed place in the tabernacle. Near the entrance of the outer court was the brazen altar of burnt offering, on which were presented all the burnt offerings and sin offerings which were not required to be offered without the camp. Farther on was the brazen laver, where the priests were required to wash their hands and feet before they entered into the tabernacle.

Within the Holy Place was the golden table of shewbread on the north side, the golden candlestick on the south side, and the golden altar of incense, with their instruments. In the Most Holy Place was the ark of the covenant, with its cover, the mercy-seat, the symbol of Jehovah's throne.

None but the priests were allowed to go into the tabernacle. They entered it twice a day; in the morning to put out the lights, and in the evening to light them; and also on the Sabbath to place the new shew-bread. The Holy of Holies was entered by the high-priest alone, and by him only once a year, on the great day of atonement. Of course there was a necessary exception to these rules when the tabernacle had to be taken down or set up.

The tabernacle was first set up by Moses on the first day of the first month of the second year from the Exodus, when the presence of God was manifested by the shekinah, which filled the tabernacle. Whenever the camp was at rest, the shekinah was over the tabernacle, as a cloud by day and a fire by night. The lifting up of the shekinah was the divine signal for the people to march; and when it again rested in any spot, there the tabernacle was set up, and the camp was formed around it. After the conquest of Palestine the tabernacle was set up in Shiloh, where it remained, with the ark of the covenant in it, till the latter was carried out to battle and taken by the Philistines just before the death of Eli. (1 Sam. iv. 16-21.) After seven months the Philistines, moved by the judgments of God, restored the ark, which however was not brought back to Shiloh, but to Kirjathjearim (1 Sam. vii. 1-2), where it remained till David brought it to the city of David in Jerusalem, and pitched a tent for its reception (1 Chron. xiii.-xvi.). Here it remained, with a short interruption during the rebellion of Absalom, till it was placed in the Holy of Holies of Solomon's temple. (2 Chron. v.)

We have no exact information respecting the history of the tabernacle during this period. By comparing 1 Sam. xxi., with Mark ii. 26, we learn that it was at Nob in the time of Saul. At the beginning of Solomon's reign it was at Gibeon (1 Kings iii.), whence it was taken by Solomon, and laid up in the Temple, at the time when he removed the ark. (2 Chron. v.)

The institution of the tabernacle was in perfect accordance with the spirit of the Israelitish constitution. Jehovah was the king of Israel; he had promised to be with them, and to go with them in their journeys; and the tabernacle was his abode. Here the glory which was the symbol of his presence was displayed, and hither the people came to worship him and to inquire his will, while his chosen servants (the priests) attended constantly upon him. (Ps. lxxxiv. 4-7.) When Israel was firmly settled in the promised land, and a special place was fixed on for the display of God's presence, the moveable tabernacle was superseded by the permanent temple. The New Testament refers to the tabernacle as typical of the blessings of the Gospel. (Heb. ix.)

TABERNACLES, FEAST OF (חַג הַסֻּכּוֹת, *ἑορτὴ σκηνῶν*, *σκηνοπηγία*), was the last of the three great annual festivals of the Israelites which required the presence of all the people in Jerusalem (Exod. xxiii., 16; Levit. xxiii. 34; Numb. xxix. 12; Deut. xvi. 13). Its object was to commemorate the dwelling of the people in tents during their journeys in the wilderness; and it was also a feast of thanksgiving for the harvest and vintage, whence it is called "the feast of ingathering." It was celebrated in the autumn, at the conclusion of the vintage, and lasted eight days, namely, from the 15th to the 23rd of the seventh month (Tisri, which corresponds to October). The first and last days were holy convocations, in which no work might be done, and the last was the greatest day of all the feast (John vii. 27). In the opinion of many biblical antiquarians, the feast of tabernacles properly lasted only for seven days, the eighth being peculiarly "the feast of ingathering." (Nehem. viii. 18.)

This feast lasted longer than either of the other great feasts; it was kept with greater demonstrations of joy, and more sacrifices were offered during its continuance. (Levit. xxix. 12-38.)

During the feast the people dwelt in booths, which were made on the tops of their houses (Nehem. viii. 16). These booths were made of the leafy branches of certain trees, which are mentioned in Levit., xxiii. 40, and include the citron, the palm, the myrtle, and the willow, though in Nehem., viii. 15, the olive and the pine are also mentioned. These booths were meant to represent the tents in which the Israelites dwelt in the wilderness. In the sabbatical year, the law was read in the presence of all the people at this feast. (Deut. xxxi. 10-13; Nehem. viii.)

Like many others of the institutions of the Mosaic law, the feast of tabernacles was neglected during the period from the settlement of Israel in Palestine to the Captivity. It was revived in the time of Ezra and Nehemiah. (Nehem. viii.)

Plutarch (Sympos. iv. 6) gives an account of the feast of tabernacles, which he supposed to be in honour of Bacchus.

The later Jews have added other ceremonies to those which are assigned to this feast in the law. 1. They carry a citron in the left hand, and a bundle of branches, namely, one of the palm-tree and two of the willow and myrtle, in the right, with which they walk in procession round the reading-desks in the synagogues, singing Hosannahs. This ceremony, which is repeated seven times on the seventh day, is said to be in commemoration of the taking of Jericho by such a repeated procession round its walls. (Joshua vi.) 2. On each of the seven days of the feast they pour out a libation of water. They assert that this was done anciently before the altar at Jerusalem, with water brought from Siloa. 3. They assert that lights were burnt in the court of the women on the first evening of the feast. These lights were in large golden candlesticks, and their brightness was visible over all the city.

TABES. This word belongs to a period in the history of medicine, when nosologists were less informed than they now are of the true nature of many diseases; and, instead of classifying these according to their essential characters in reference to the single standard of healthy function, selected and arranged such signs and appearances only as were sensibly manifest to the observer, or were described by the patient. The nomenclature founded on this arrangement consisted in naming by uninterpreted symptoms: it involved many breaches of natural affinity, and gave great opportunity for empirical practice. Thus a cough, a dropsy, a palpitation of the heart, would be spoken of as individual diseases; whereas they may on the one hand be joint symptoms of a single malady (as imperfect valvular action of the heart); or, on the other hand, taken singly, each would be but a sign, common to many disorders, which might have no other feature of resemblance, and might require even opposite treatment. Such a name is "tabes," and under it are isolated certain symptoms, afforded by the nutritive functions in various conditions of unhealth: the acceptation of the word being a "cachexia (or state of chronic ill-health) attended by emaciation;" in which sense it is synonymous with the words "atrophy" and "marasmus."

TABES MESENTERICA. This name is applied to a particular slowly-disorganising affection of the mesenteric glands, and expresses the marked emaciation which attends the disease. It is through the mesenteric glands that the nutritive products of digestion are transmitted in their course to the great current of the circulation; and any disorder which destroys or obstructs these organs must, in proportion to its intensity, affect their function, and derange the process by which healthy materials of renovation should constantly be commingled with the blood. Hence in part arises the loss of flesh in this form of tabes; but the direct hindrance of nutrition which the disease involves is not the sole, though an important cause of the symptom; for the general ill-health, of which tabes mesenterica is but a part, and other co-existing complaints, usually co-operate in producing it.

The disease is one among many manifestations of scrofula; and is essentially the same to the glands of the mesentery as those obstinate glandular enlargements of the neck, with which the eye is more familiar, are to their region of the body. From difference of position and of relations it includes other symptoms and graver consequences than theirs; but it originates in the same constitutional tendencies, and follows the same general progress. It belongs, like other forms of scrofula, to early life; the ordinary period of its invasion being from the second to the twelfth year. In the Hôpital des Enfans, of Paris, children are received from a year after birth till the completion of sixteen years of age; and M. Guersent, the physician of this institution, states that the disease exists among those admitted in the proportion of 7 or 8 to 100; and that it is more frequent among female children than among males.

The morbid appearances on dissection of fatal cases are, a more or less complete transformation of the glands into tubercular masses, with various consequent or coincident diseases of the adjoining organs. The glands appear at the commencement of the complaint to be the seat of a feeble inflammatory action, under which they merely swell and become preternaturally reddened with blood; but this stage of simple congestion soon induces a further change, in which the characteristic product of scrofulous inflammations becomes deposited in the tissue of the gland. The dull white granular tubercles, by which the infiltration commences, are gradually multiplied in number or increased in volume; and, in like proportion, the glandular substance itself is absorbed to make room for the encroaching disease, till at length a rounded tubercular mass results, varying for each tumour from the size of a marble to that of an egg. In a still more advanced condition of the disease suppuration frequently occurs in these tumours, and they are then seen to contain the cheese-like matter of softened tubercle mixed with pus. The abscess so formed excites irritation in its neighbourhood; the folds of peritoneum covering it become glued together, and its progress occasionally extends to discharging itself into the nearest intestine, or through the external integument of the abdomen. A certain amount of inflammation of the peritoneum, with adhesions and effusion of serum (ascites), attends these latter stages; and some inflammation and ulceration of the mucous membrane of the intestines are likewise frequently found.

For a particular account of its causes the reader may refer to those of SCROFULA. Original weakness of constitution, shown in general susceptibility to the impressions of disease, in slowness and insufficiency of reactive and reparative power, is the groundwork of these, and constitutes the main peculiarity of the so-called *scrofulous diathesis*. But this weakness may, where inborn, be aggravated, or, where naturally absent, be artificially produced by a variety of depressing causes; by insufficient or unhealthy food, by neglect of cleanliness and exercise and clothing, by residence or constant occupation in ill-ventilated buildings, by exposure to cold and damp: all of them influences to which the young of the poor in crowded towns are exposed, and with which too frequently an inherited predisposition powerfully co-operates. Derangement of the bowels must be considered the most freuqent special cause of this particular form of scrofula; the irritations, inflammations, and ulcerations of their mucous surface (of which such full evidence is given in the state of the tongue and excretions, and in the tympanitic abdomen) excite corresponding conditions in the absorbent glands connected with them (precisely as a lesion of the hand irritates the glands of the axilla), and the inflammation so beginning takes a course determined by the peculiar constitution of its subject.

As regards symptoms, it may be observed that in its earliest stages the disease has no signs by which it may be certainly distinguished; that it is not till the glands are so enlarged as to become sensible externally that their affection can be positively declared. The early symptoms are those of the intestinal disorder or irritation, which is acting as a cause of the disease: capricious appetite, irregular and unhealthy stools, flatulence or occasional vomiting, loaded tongue, foul breath, harsh skin, sallow complexion, and loss of flesh, with an accelerated pulse, may have existed for some time, before enlargement of the abdomen attracts notice. It will then usually be found that steady pressure on this part causes uneasiness or pain. As the growth of the glanular tumours continues, the signs of intestinal disease become more marked; diarrhœa with mucous stools, increased emaciation, frequent pulse, and evening accession of fever, marking this stage, in which the tumid abdomen contrasts remarkably with the wasted limbs and shrunken wan face of the patient. Finally, hectic fever with exhaustive diarrhœa, or acute abdominal inflammation, or the progress of the constitutional disease in other organs, or absolute starvation (atrophia), terminates life.

The treatment of tabes mesenterica must be in accordance with the general rules for management of scrofula, and consists in that modified tonic system, to which the name of "alterative" is given. [SCROFULA].

TABLATURE, in Music, is the old mode of notation for instruments of the lute kind. For this purpose six parallel lines were used, each representing a string, on which were placed letters referring to the frets on the neck of the instrument. The time, or duration, of the notes was marked by characters over the letters, answering to the minim, crotchet, &c., and often, as by Mace, in his 'Musick's Monument,' by the notes themselves. There were different systems of Tablature; but the subject is not now worth the trouble which a knowledge of it would demand.

TABLE.* By a table is meant a quantity of information arranged under heads in such manner that by looking under one head the general disposition of the whole points out where to look for the matters of information connected with that head: the object being an immediate power of reference to any one fact or result without the necessity of looking at others. In any astronomical table, the matter by which we enter the table to look for other matter is called the *argument;* that which is found by means of the argument has no distinct name; we might call it the *tabular result*. It would be useful to generalise these terms. Thus in a table of contents, the number of the page or chapter is the argument, and the abstract of the matter contained is the tabular result: in an alphabetical index the principal word, found by means of its first letter, is the argument; and the number of the page in which the matter is contained is the tabular result. It is, unfortunately, useless to say much on any tables except mathematical ones. Works containing collections of facts, in which the tabular form ought to be frequently used, are in most instances altogether free from them: and as to indexes, the art of making them seems to be lost; very few books, except those on law, have anything deserving the name. The reason is obvious enough: where proper information is not given, the table shows the spot where it ought to be, *vacant;* and a good index points out not only what *is* in the work, but also that which *is not.* For instance, to take a table which we should only have inserted in this article in mere illustration, the 'Numerorum Mysteria,' of Peter Bungus (2nd ed. Bergomi, 1591) is a table of numbers. The argument is the number sought, the tabular result is a list of the hyper-arithmetical properties of the number. Thus, turning to 666, we find all the modes of interpretation which a zealous adherent of Rome could give, including Martin Luther, who satisfies the equation, both in Latin and Hebrew, as perfectly as the average run of solutions. But 667 is not in the table; so that we see it has no mystery about it.

---

* Throughout this article all works which we describe from actual inspection have the dates uninclosed: all works which we take from others have the dates ( ) in parentheses.

When the matter sought for is found by one argument only, the table is said to be of single entry; when by two, of *double entry.* Thus the common multiplication table is one of double entry; and so is any chronological table which consists of more than one column.

A table is, of course, used after the manner of a dictionary; and the chief plague attending the use is the constant turning of the leaves. The trouble which this gives may be lessened by cutting off successive lengths on the right-hand margins, as is done in the indexes to ledgers, and in other works of reference. We have tried this on a table of logarithms (of the Useful Knowledge Society, 1839) taking the common logarithms, and making the cuttings so as to show a little bit of every alternate leaf. Enough of the leaf is shown to enter four figures of the primitive with which it begins in black ink, and four figures of the logarithm in red ink. The saving of trouble is so decided that no person who has experienced it will ever again allow a table *which he frequently uses* to be without this contrivance. So soon as the advantage is understood, tables will have the proper references printed on the proper parts of the margin, the binder being left to cut away the supervening strips. The same object might be gained by protruding slips of vellum pasted down the margin, if the boards of the book were made to extend beyond the margin sufficiently to protect the slips; this also we have tried with good effect. We can assure those who are constantly in the habit of using logarithms that they may make this hint give a greater facilitation than has ever been proposed since the time when Briggs brought forward his modification of Napier's system.

Mathematical tables may be divided into *conclusive* and *subsidiary:* conclusive, such as the table of squares, in which the tabular result is the object of the reference; subsidiary, such as the table of logarithms, in which the tabular result only facilitates the object. Conclusive tables can be easily used by those who want them but seldom: subsidiary tables are not much used, except by those who want them more frequently. The reason is that a subsidiary table which is not often wanted has its *modus operandi* forgotten between uses; or at least the possessor feels a want of practice, and a necessity for referring to the directions, to be sure of his result. The best thing to be done, when a person first takes to a new subsidiary table, is for *himself* to write in the book *his own* account of the method of using it, so soon as he has learnt it, with some examples. This reference he will find, on future occasions, to be more suggestive to his memory than anything which the writer of the book has said or could have said.

The method of printing mathematical tables is usually defined so closely by the nature of the subject, that no remark is necessary except on the type. The numeral characters, up to about the year 1785, used to be smaller in the body than those now constructed, with distinguishing heads and tails. Dr. Hutton, we believe, first employed the character in which all the numerals are of the same depth, the heads or tails being compressed into the body. This very disadvantageous change was adopted by the type-founders, but for a long time only in England: the consequence was that the superior legibility of the ancient and of the modern continental tables was matter of common remark among those who had to use them. Another circumstance which contributed to this result was the introduction of numerals with thick and thin parts, the superior elegance of which was supposed to be a recommendation. The consequence was, that in many English tables it was difficult to distinguish 3 from 8, and 9 or 6 from 0. Of late years however, many works have been published which have used the old type, both as to heads and tails and uniform thickness;[*] and their decided superiority over tables of the Huttonian character, even of much larger type, is pretty generally admitted. This is a point of great importance: for any circumstance which produces a wrong result upon the computer's paper is equally to be deprecated, whether it be an error in the formula used by the author of the tables, or an incorrectness of the printer or reviser; and in like manner a given amount of tendency to error is of the same bad consequence, whether it be due to the mathematician or the type-founder. This is not true of works of theory or reasoning: it may there be the fault of the reader if he do not correct a mere slip, whether of the author or printer; but in works of tabular reference *all the parties to the result are of equal importance.*[*]

The restoration of the old numerical type, namely, that in which all the figures except 0, 1, 2, have a head or a tail, and in which the thickness does not vary sensibly from one part to another, was adopted and recommended by the Astronomical Society at the end of 1842; but it had previously been used by Mr. Baily in his detail of the Cavendish experiment, which forms one volume of the Memoirs of that Society. The writer of this article, who first suggested the revival of the old figure (and caused it to be employed in Taylor and Walton's five-figure logarithms, in their reprint of Barlow's tables, and in his own work on Arithmetic, before any one else had used it), is decidedly of opinion that one more change is yet wanting, the substitution of dull and rather dark paper for the bright and shining material now in general use, which dazzles the eye too much. Tables should not be hot-pressed, and not even pressed at all. The mischiefs of pressure are two-fold; first, the smooth surface thereby created makes the page a kind of mirror, which has a bright image in one place, whereas rough paper dissipates the light equally in all directions; secondly, the other side of the leaf shows through much more after pressure than before. It is also a mistake to suppose that great blackness in the ink, combined with great whiteness in the paper, is favourable to the reader. Every increase of the contrast, over and above what is necessary to perfect legibility, is injurious to it: jet upon snow would in time destroy the strongest eyes. Of all the things which are meant to be read, a black monumental inscription on white marble in a bright light is about the most difficult: one would suppose, to look at our specimens of expensive printing, that such an inscription was the model which it was intended to imitate, and if possible to surpass. We are satisfied, after many trials and comparisons, that a dull paper, of a whitish-brown character, too thick to be seen through, and an ink which is of a dull-brown black, as it were the very deepest shade of the colour of the paper itself, are the things which are permanently agreeable to most eyes. Those who try it should remember that the first page read is not so good a test as the hundredth.

One of the most legible books we know of is the trade edition of Gibbon's 'Decline and Fall,' &c., in twelve volumes octavo, London, 1820. It is considered by the booksellers themselves to be very badly executed. But printers and publishers are too much in the habit of forgetting that a book is a book and not a line engraving. They look at the page as a whole, and if the individual lines stand out and make their separate existences too perceptible, they pronounce it ugly. Accordingly, the uglier they hold it to be, the more legible the reader will pronounce it. We have seen more than one printer and publisher hold a page at such a distance from his eye as made it impossible for him to read it, as a means of judging of the *general effect.* Surely a printed page is meant to be a congeries of *particular effects,* each as distinct from the other as possible.

We regret to see that, just as we have nearly abandoned the use of the thick even-sized figures, the Germans are taking strongly to them. Most of the modern German tables have these illegible characteristics.

Since the invention of logarithms, the appetite for tables has not grown with the progress of mathematics. Calculation by logarithms is so convenient for ordinary purposes, that many persons who are even well versed in mathematics are not aware how much assistance they might derive in particular cases from the various tables which have been published. The list which we mean to give does not profess to be a bibliography of tables, but will nevertheless give information on the subject to all who are not particularly given to mathematical bibliography.

We may divide mathematical tables into general and special; the first consisting of purely arithmetical and trigonometrical tables, and also tables of logarithms. The special tables are those which are used in the higher parts of mathematics, in commerce, navigation, astronomy, meteorology, &c. We may further divide tables into tables of facts and tables of mathematical results. All sciences have their tables of facts; thus the raw observations of astronomy, magnetism, and physics in general are frequently tabulated: with these we have comparatively little to do; since they are rather the materials for the formation or verification of other tables, than of primary use as tables.

---

[*] In the new series of the 'Nautical Almanac,' the heads and tails first re-appeared, but the swelling of the type was not rejected. The works in which the old legibility was first completely restored were, so far as we know, the tables of logarithms (four and five figures), and the reprint of Barlow's Tables (Taylor and Walton), the six-figure logarithms (Longman), and Lieut. Raper's 'Elements of Navigation.' Thus it stood when the 'Penny Cyclopædia' was published. The legible figures are now common enough in England: but Germany is infested with the illegible ones. The swelling type has been rejected in the 'Nautical Almanac,' which is now as legible a tabular work as exists, as to both print and paper.

[*] So we said in the 'Penny Cyclopædia': we now incline to think that *the printer is the most important of all.* One of his errors may be equal to many of the author's. For instance, in Chernac's table a line fell out, probably just before press: it was put in again at the top of its compartment instead of at the bottom. The consequences were 26 gross errors, of a far worse kind than the author could have made, unless he had tried. Burkhardt found but 10, besides this set, in the whole book; and of these one was only 23 × 19 instead of 19 × 23, and two others were clearly due to the printer at press. Chernac's work has 1020 large quarto pages full of figures, or lines of equal importance.

Of simple arithmetical tables we may notice the following:—

§ 1. *Tables of multiplication.*—The oldest we know of is as follows:— Tabulæ Arithmeticæ ΠΡΟΣΘΑΦΑΙΡΕΣΕΩΣ[*] Universales . . . . E Museo Johannis Georgii Herwart ab Hohenberg V. I. Doctoris. Munich, 1610, folio. This table goes up to 1000 × 1000; each page taking one multiplier complete. There are then a thousand odd pages; and as the paper is thick, the folio is almost unique in thickness. There is a short preface of seven pages, containing examples of application to spherical triangles. It is truly remarkable that while the difficulties of trigonometrical calculation were stimulating the invention of logarithms, they were also giving rise to this, the earliest work of extensively tabulated multiplication. Herwart passes for the author, but nothing indicates more than that the manuscript was found in his collection. The book is excessively rare; a copy sold by auction a few years ago was the only one we ever saw.

There have been several others of great extent, but they are scarce. Hutton's 'Tables of Products,' printed by the Board of Longitude, 1781, go up to 100 times 1000, but have not the reputation of correctness. An anonymous table, London, 1775, which goes up to 10,000 × 10, is 'Tables of Products . . . London, printed for J. Plummer.' But Riley's table, published in the same year, under exactly the same form, is 'Riley's Arithmetical Tables . . . . London, printed for G. Riley.' It is imperfect in all the copies we have seen, ending abruptly at the multiplicand 5280. The numerals are of the same form and size as in Plummer, but the headings and lines are different. We suspect that some writer of more than usual research on the quarrels of authors, or some hunter of old injunction[†] cases, might find something about the history of these two books. The type is clear, and the tables are very useful.

Dodson's 'Calculator,' London, 1747, has the same as the last up to 1000 × 10, not so conveniently arranged. But by far the most powerful table of this kind is Crelle's 'Rechentafeln,' Berlin, 1820, in two thick 8vo volumes. This contains every product up to 1000 times 1000, so arranged that all the multiples of one number are seen at the same opening of the book. All who have used this table know how to dispense with logarithms in many cases with great advantage. There is no table which we so much desire to see reprinted in this country, with a few alterations, which would render it more commodious. Another edition was published by Dr. C. Bremiker, Berlin, 1857, folio; but we are told that other copies bear the date (1859), and, we believe, no editor's name. Each page here contains the 999 multiples of two numbers; giving 450 pages of tables. This edition is very convenient, and of very comfortable type and paper. An anonymous Table, Paris (1794), goes up to 1000 × 103; and another, Paris (An VII.), the same; a third, Versailles (1825), the same, with many meteorological tables added. Schubler's 'Rechnung's Lexicon,' Nuremberg (1739), goes to 2400 × 100. Oyon's Table, Paris (1824), goes to 509 × 500; that of Cadet, Paris, 1801 or 1802, An X, to 10,000 × 100. This work of Cadet was intended for a *ready reckoner and percentage table.* Each number from 1 to 10,000 has its first hundred multiples in one folio column. Citizen Cadet was a tax-gatherer, and saw that, in a decimal system, a raw table of multiplication is a *Barême*, or ready-reckoner, quite complete. Accordingly, the title of his book is 'Tarifs des Centimes au franc, ou Tables de multiplications et comptes-faits pour la répartition des contributions, et pouvant remplacer, dans le systême décimal, les anciens comptes-faits de Barême.'

Bretschneider, 'Producten-Tafel,' Hamburg and Gotha, 1841, goes up to 100,000 × 10. There is a compression of this kind: in finding, for example, the multiples of 62873, the reader must look into the page headed 2800, and there, in one part of the page, opposite to (6) 28, he finds the first three figures, and in another part, opposite to 73, the last three figures. The first part, belonging to 628, is repeated twice, once for the cases in which the following numbers are less than 50, and once for those in which they are above it; and an asterisk in the last part of the table occurs when it is necessary to add a unit to the preceding figures. This arrangement brings the table into ninety-nine pages octavo, and is very ingenious; but there is more risk of error in using it than we like. Again, multiplying five figures by one is not so difficult an operation that it need be avoided by using a table which requires us to look attentively at three distinct things, after turning pages. Lambert's table, 1770, presently mentioned, contains the nine multiples of sin x for every degree, to six figures; and multiples of primes to those of 313. Pohlman's Table, 1813 (2nd ed.), contains the first nine multiples of all numbers up to 1000. We have heard of another work of Crelle, 'Erleichterungs Tafeln,' in oblong folio, giving all numbers under 10,000,000, with their nine multiples, but with an arrangement not easily nor safely used. There is a double process, as in Bretschneider.

In the Royal Society's Library is a table by J. J. Centnerschwer, 'Neu-erfundene Multiplikations-und-quadrat-Tafeln,' Berlin, 1825. The earliest table we have seen mentioned (by Lipenius) is Thomas Finck, 'Tabulæ Multiplicationis ac Divisionis,' Copenhagen (1604), oblong form. There is also, by the same author, 'Tabulæ quotidiano numerandi usui accommodatæ,' Copenhagen (1615), 16mo.

As Finck is an author of some interest in the history of tables (as will presently appear), we have made some inquiry about these works,[*] and we find that they are not in the library at Copenhagen; but that Mollerus ('Cimbria Litterata,' vol. iii., p. 254), gives them as follows. It seems they were not intended for scientific purposes:—

'Tabulæ Multiplicationis et Divisionis, seorsim etiam Monetæ Danicæ accommodatæ,' Hafniæ (1604), oblong folio.

'Tre Tabeller, indrettet til daglig fornöden Regning.' (Three tables accommodated to necessary daily accounts). Copenhagen (1615), 16mo.

Under this head we ought to mention John Bernoulli (the younger), 'Sexcentenary Table,' London, 1779, and Michael Taylor's 'Sexagesimal Table,' London, 1780, intended to save the use of logistic logarithms; the former having 10′ for the first term, and the latter 1°. Both were published by the Admiralty. In the day of sexagesimals, tables of multiplication were common in which the products were converted sexagesimally; as in Orontius Finæus, 'Arithmetica Practica,' Paris, 1555, in which is a table up to 60 × 60. But the multiples of 46, for example, are 0′ 46″, 1′ 32″, 2′ 18″, &c. The bibliographer should remember that when a sexagesimal table is pasted into a copy, it does not follow that it formed part of the work: owners often pasted in a table from another source.

Under the head of Multiplication, we must notice tables of QUARTER-SQUARES. The earliest we have seen (and we believe the earliest known to exist) is that of A. Voisin, Paris, 1817, 'Tables de Multiplications,' &c., 8vo, containing quarter-squares of numbers up to 20,000. Leslie reprinted this table up to 2000, in his 'Philosophy of Arithmetic' (2nd ed.), 1820, as (according to Mr. Laundy) did Galbraith, as far as 3149, in the second edition (1836) of his 'Mathematical Tables,' J. M. Merpaut, 'Tables Arithmonomiques,' Vannes, 1832, gave quarter-squares up to that of 40,000. But the largest and most valuable set of these tables yet published is that of Mr. S. L. Laundy, a London actuary, 'Table of Quarter-Squares,' 1856, 8vo, which goes to 100,000, and is beautifully printed. Colonel Shortrede, one of the most energetic of tabulators, has computed this table to 200,000, but has not published it, though we understand he intends to do so. We suggest to him to publish the second half first.

§ 2. *Tables of Division and of Prime Numbers.*—Fr. Schooten, in book v. of his 'Exercitationes,' 1657, gave all the primes under 10,000. Gruson, 'Pinacothèque,' Berlin, 1798, gives for all numbers under 100, or primes under 400, the quotient and remainder of every number under ten times the divisor, by inspection: also, primes and lowest divisors up to 10,500. Lidonne, 'Tables de tous le Diviseurs,' &c., Paris, 1808, gives the divisor of all numbers up to 102,000. The original edition of Barlow's Tables gives the factors of all numbers up to 10,000 and a register of prime numbers up to 100,103. Chernac, 'Cribrum Arithmeticum,' &c., Daventriæ, 1811, gives the prime numbers up to 1,020,000, and all divisors of numbers not divisible by either 2, 3, or 5. Burckhardt, 'Table des Diviseurs,' &c., Paris, 1817, gives the prime numbers up to 3,036,000, with the lowest divisor of each number when not either 2, 3, or 5. These useful works are now rare. Anjema's 'Tabula Divisorum,' Leyden, 1767, goes up to 10,000, and Pigri's Table, Pisa (1758), which Chernac had never heard of, the same. Anjema enters *every* divisor: thus, 2 is entered as having two divisors, 1, 2. He also separates those less than the square root from the others by a hyphen; and where the number is a square, the root has a hyphen on both sides. Krause, Jena and Leipsic (1804), has primes and factors up to 100,000. J. Neumann, 'Tabellen,' &c., Dessau (1785), has factors and primes up to 100,100.

Guldinus is said to have given tables of prime numbers, but we have neither found them nor a description of them. Thomas Branker appended to his translation of Rhonius's Algebra a table of primes and divisors for all numbers under 100,000. This was reprinted by Baron Maseres, and was appended to his tract 'On the Doctrine of Permutations and Combinations,' London, 1795, a book very easy to be obtained.

This translation of Rhonius is of London, 1668, "much altered and augmented by D. P.:" this D. P. is Dr. Pell. The table of primes, &c., to 100,000 is computed under Pell's advice and direction; and a great part, it is believed, by himself. But there is preserved in several places the title of a work of Pell which we have never seen, and which we take from Lipenius: 'Tabula decem millium difficilium Numerorum, eorum nempe omnium qui ab 0 ad centum Milliones [mille?] habent difficultates,' English, London, folio, (1666). This looks like a table of prime numbers, and the number of primes under 100,000 is about 10,000. But we must leave it to those who can see the work, if it still exist. Branker's table was reprinted in the second volume of Harris's 'Lexicon Technicum,' London, 1710.

---

[*] Prosthaphæresis is a word compounded of prosthesis and aphæresis, and means addition or subtraction. Astronomical corrections, sometimes additive and sometimes subtractive, were called prosthaphæreses. The constant necessity for multiplication, in forming proportional parts for the corrections, gave rise to this table, which therefore had the name of its application in the title-page.

[†] The following gives a strong suspicion. In our copy there is a preface of fourteen pages, signed "The Editor." The late Mr. Woolgar, who made tables a special study of great depth, had a copy in which a preface of fourteen pages was signed "William Webb," whose name was also in the title. Our preface has only—"Our tables . . . . are carried to nearly twice the extent of any tables of the kind hitherto published:" Mr. Woolgar's preface has—"There have likewise been published this year by Mr. Riley, Arithmetical Tables, containing the products of all numbers from 1 to 5280, and are a set of very useful and correct tables; the errors of the press are very few, the form of them we have also thought convenient, and it is that which we have adopted." We surmise that W. Webb played Vlacq to Riley's Briggs as soon as Riley's tables were published, and that legal proceedings were compromised by an arrangement of which it was a portion that handsome mention should be made of Riley's tables in a new preface, with the editor's name.

[*] From Professor Werlauff, Royal librarian at Copenhagen, through the kindness of the late Professor Schumacher, the universal referee of those who wanted information on any point connected with astronomy, however remotely.

Vega (Octavo Logarithms, vol. ii.), 1797, gave primes and divisors up to 102,000, and further primes up to 400,000, in which Chernac found but 39 errors.

Chernac mentions primes and divisors to 10,000, in the Arithmetic of T. M. Poelius, Leipsic (1728), 8vo, reprinted in Richter's 'Lexicon Mathematicum;' primes to 101,000 in Kruger's Algebra (1746); primes to 100,000 from Kruger, in a separate work of Lambert, not the logarithmic and other tables of 1770; primes to 400,000, by A. F. Marcus, Amsterdam (1772), 8vo.

Murhard mentions the *first part* of a table (by A. Felkel) of the factors of all numbers not divisible by 2, 3, or 5, from 1 to *a hundred millions*, Vienna (1776). Chernac alludes to this table as mentioned by Krause, but had never seen it.

§ 3. *Tables of Squares, Cubes, Square Roots, Cube Roots, and Powers in general.*—Perhaps the oldest printed table of squares is that in p. 30 of Pacioli's 'Summa,' &c. [VIETA, in BIOG. DIV.], printed in 1494, and again in 1523, which, however, goes only to 100^2. Cosmo Bartoli, 'Del Modo di misurare le Distantie,' &c., Venice, 1564, has squares up to 661^2. Maginus's 'Tabula Tetragonica,' Venice, 1592, is not a separate work, but a chapter in his work on triangles, presently mentioned: it gives squares up to $10,100^2$, but not cubes. It was, however, published separately, at the same time with the work on triangles, as well as in it: the only difference being that the separate publication has its headings and explanations Italian instead of Latin. The number of so-called books, which are only chapters of other books, is large enough to make a big catalogue.

Guldinus, 'De Centro Gravitatis,' Vienna, 1635, gives the squares and cubes up to those of 10,000. The founder of the modern Encyclopædia, Alsted, 1649, gives squares and cubes up to 1000. Pell, London (1666), (Murhard), squares to that of 10,000. William Hunt, 'Gauger's Magazine,' London, 1687, gives a table of squares up to that of 10,000. A few pages of this work are Newton's. Ludolf, 'Tetragonometria Tabularia,' Frankfort and Leipsic, 1690, 4to, gives the squares up to that of *a hundred thousand;* the largest table of squares in existence, and very little known. J. P. Buchner, 'Tabula Radicum,' &c., Nuremberg, 1701, gives squares and cubes up to those of 12,000. Hutton (table in § 1) gives squares up to that of 25,400, and cubes up to that of 10,000. Lipenius mentions 'Tabulæ numerorum quadratorum decies millium,' Londini (1672), which is Pell's table, though it has not his name. It has also an English title, contains the first ten thousand squares, and also the number of pairs, triads, and quaternions (1044 in number) of figures with which a square can end. Henischius, 'Arithmetica perfecta,' Augsburg, 1609, begins with squares and cubes of all numbers up to 360. Heilbronner (p. 627) mentions a *tabula Calriana* which gives squares up to 1000^2. Detached tables of powers are given in various works. John Hill's Arithmetic, of which the seventh edition bears London, 1745, has all the powers of 2, up to the 144th, for the purpose of solving questions about chessboards and horseshoe nails. We have also the title G. C. Sartorius, 'Cubische Tabellen,' Eisenach (1827).

Dodson's 'Calculator' (§ 1) gave square and cube roots up to those of 180: Hutton afterwards gave the same up to those of 1000. Barlow, 'Tables,' London, 1814, gave squares, cubes, square roots, cube roots, and reciprocals, up to those of 10,000; the roots to seven decimal places; the reciprocals to seven significants. These were reprinted (London, Taylor and Walton, 1840), from the original, after re-examination by Mr. Farley. Tables of squares and cubes, up to those of 10,000, were reprinted from Séguin's 'Manuel d'Architecture,' with a descriptive preface, at Paris, about the beginning of the century. This table has beautifully clear figures, of 24 to the inch, of thin and even body, with heads and tails. It was this table which first suggested to the author of this article the superiority of the numerals with heads and tails, and gave rise to his suggestion to the Useful Knowledge Society, 1839, to reprint Lalande's Table in such a figure. The example is now extensively followed. Meinert's Logarithms, Halle (1790) contain squares and cubes up to those of 1000. Bochert, 'Tafeln,' &c., Leipsic (1812), goes to the square of 25,200, the cube of 1200, and the square and cube root of 1000. Beyens, Ghent (1827), goes to the square of 10,000, and the cube of 1000. Schierk, 'Tafeln,' &c., Rohn om Rheim (1827), has squares up to that of 10,000. Merpaut, in the work above mentioned, gave reciprocals up to 10,000, to nine significants.

Joncourt, 'De la Nature....de Nombres Trigonaux,' Hague, 1762, gave triangular numbers up to that of 20,000, cubes up to that of 600, and showed how to use the former in the construction of squares and square roots. As to higher powers than the third, Hutton and Barlow, in works above cited, give every power of every number up to the tenth power of 100. Barlow gives also the fourth and fifth powers of numbers from those of 100 to those of 1000. Bowditch (work of 1834, cited under 'Logarithms,' 1757) gives square roots to five decimals ·000 (·001)4·200 (·01)10·19 with tables of proportional parts.

Maseres, at the end of the tracts on Combinations, London, 1795, has reprinted Hutton's square roots 0(1)1000 to ten decimals, and reciprocals to seven. We believe that Hutton first gave them in his 'Miscellanea Mathematica,' 4 vols. 12mo, 1775. In Jonas Moore's Arithmetic, 1650, there are the squares and cubes of all numbers up to 1000, the fourth powers up to 300, and the fifth and sixth up to 200. These were reprinted in the edition of 1560.

Rogg mentions 'Art gantz neu-entdeckte,' &c., Dessau (1755), 8vo, containing the cubes of all numbers up to 100,000, or at least professing in the title-page to give the cube root of every number under a thousand millions of millions: perhaps the cubes went to that of 10,000, with a rule for the fifth figure. And here we may mention that we have been several times deceived by a title-page stating, not the extent of the table, as it ought to do, but the extent to which operations of interpolation or accession will be effective.

§ 4. *Pure Decimal Operations.*—Besides Barlow's reciprocals (§ 3), the only remarkable tables of which we know under this head are Goodwyn, 'Table of the Circles arising from the Division of a Unit,' London, 1823, and 'Tabular Series of Decimal Quotients,' London, 1823 (both anonymous). The first gives all the circulating decimals which can arise from any fraction whose denominator is under 1024; the second arranges all fractions which in their lowest terms have a numerator not exceeding 99, and a denominator not exceeding 1000, in order of magnitude, and gives their equivalent decimals to eight places. Mr. Woolgar is our authority for saying that there was a previous work by Goodwyn, 'First Centenary of concise and useful Tables of Decimal Quotients' (1818), 4to. Mr. Goodwyn (of Blackheath) was an indefatigable calculator, and the preceding tables are the only ones of the kind which are published. His manuscripts, an enormous mass of similar calculations, came into the possession of Dr. Olinthus Gregory, and were purchased by the Royal Society at the sale of his books in 1842.

R. Picarte, 'La Division réduite à une Addition,' Paris, 1861, 4to, gives, for all numbers up to 10,000, ten significant figures of reciprocal, with the nine multiples of each.

An anonymous work, 'Tafeln zur Verwandlung aller Brüche,' &c., Oldenburg, 1842, gives every fraction less than unity whose denominator does not exceed three figures, nor its numerator two, to seven places of decimals. It is arranged by numerators: that is, all fractions of one numerator are in one double page. This is a useful table. We may also mention (but not as having seen it) W. F. Wucherer, 'Beyträge zum allgemeinen Gebrauch der Decimalbrüche,' &c., Karlsruhe (1795), 8vo.

The oldest table we have found printed in English is in 'This boke showeth the maner of measurynge of all maner of lande, as well of woodlande, as of lande in the felde, and comptynge the true nombre of acres of the same. Newlye invented and compyled by Syr Rycharde Benese Chanon of Marton Abbay besyde London. Printed in Southwarke in Saynt Thomas his hospitall by me James Nicolson.' There is no date, but Nicolson's dated works run from 1536 to 1538. There is another edition (which omits the tables), printed by Thomas Colwell, who printed from 1558 to 1575. They are double-entry tables of the rudest character, for finding the number of acres in a given length and breadth, and for casting up payment at per perch, per acre, &c.

§ 5. *Pure Trigonometrical Tables.*—This section and the next form almost the whole of the article; and for a sufficient reason. The history of the trigonometrical canon, and of the logarithmic table, are constituent parts of the history of the progress of mathematics: the history of other tables has nothing to do with that progress, except only in the case of Stevinus's tables of compound interest, which, as will appear, suggested decimal fractions to their author. The bibliographical history of the early part of the trigonometrical canon is so incorrectly given, as well as ambiguously, even by the best authorities, that it will be worth while to collect the several heads, distinguishing between what we know from the books themselves and what we are obliged to take from other sources, by putting the name of an authority (of which we have usually two or three) to the latter. Much confusion has arisen from the double meaning of the word *publication* in regard to works of the century following the invention of printing, when it was applied equally to the issue of a printed book and of a manuscript. We are here only concerned with the former; and it is sometimes difficult to distinguish between the two.

The earliest trigonometrical table existing is the table of chords in the first book of Ptolemy's Syntaxis or Almagest. It is by half-degrees up to 90°, and thence by degrees. The chords are given sexagesimally, to a radius of 60°: thus, the chord of 90° is 84° 51′ 10″. The thirtieth parts of the differences are annexed: thus, the earliest table has its *differences*, and differences given by the convenient sub-multiple which would probably be thought very modern.

That Albategnius [ALBATEGNIUS, in BIOG. DIV.] had substituted sines for Ptolemy's chords,—that he had also used versed sines and tangents,—that Purbach and Regiomontanus had constructed and issued (in manuscript at least) tables of sines to two separate radii, 6,000,000 and 10,000,000—are historical facts of notoriety. Our question is, what tables were first *printed?* On the books which Regiomontanus actually printed, out of the long lists of those which he published and intended to publish (as set forth in his own 'Index Operum,' &c., printed at Nürnberg by himself), his historians, Doppelmayer, De Murr, Weidler, &c., are either not very clear, or somewhat at variance. In the vague manner in which books and their contents are frequently described by professedly mathematical writers, a good resource[*] is often found in the catalogues of general bibliographers.

The 'Tabulæ Directionem Profectionumque' of Regiomontanus were published by himself at Nürnberg, without date, probably about (1475), and were reprinted at Venice in (1485). We cannot ascertain that either of these contained tables of sines. But Hain ('Repert. Bibliogr.'), who gives their titles, gives that of the next edition, Augsburg, Ehr. Ratdolt (1490), 4to, in a fuller manner: from which it appears that there is appended to it a table of sines to minutes, in words which would imply that Regiomontanus had not given such a table in the former edition: they are, 'Tabella Sinus recti: per gradus et singula minuta divisa. Ad Tabulas Directionum Mag. Joh. de Regiomonte necessarias.' But from the description it is clear that this table does not belong to the work, since it follows even the printer's insignia. And Hain also met with it as a separate work; being, as appears from his description of the lineation, pages, &c., absolutely the same as that which was appended to the Tabulæ Profectionum. Accordingly, until something earlier or more definite is produced, we must say that the first known printed table of sines is an anonymous table, to minutes, in quarto, without date, but before 1500, stated (with *necessarias* when it ought to be *necessaria*) to be necessary to the tables of Regiomontanus, and implying that sines had not then been printed with those tables. From the next-mentioned edition of the Tabulæ Directionum (this we have seen) we should suppose that these tables were to a radius of 600,000, as in that edition, which is of Venice, 1504, 4to. In it we find a minute-table of sines, headed 'Incipit tabella sinus recti,' and with a column containing differences for ten seconds. Delambre and others mention Regiomontanus as having given the first table of tangents in this work under the name of *tabula fœcunda*. It is in the edition of 1504, and was reprinted by Gemma Frisius in his book 'De Radio Astronomico,' Antwerp, 1545. It is to degrees only, and to a radius 100,000; and is a table of cotangents, not of tangents. The Tübingen edition, 1550, also distinguishes the table of sines as an addition, in the title-page. The radius is now 60,000; but, by an oversight, the differences to ten seconds are entered from some table with a radius of 6,000,000, from which the table of 1550 was probably cut down. There is no *tabula fœcunda*. Delambre mentions an edition of the work, edited by Gauricus, in (1524), as containing a table of sines to every ten minutes: of this we can find nothing.

As yet we have no sines calculated to the now ordinary radius of 10,000 &c. Of these, the earliest we have seen (and we find no earlier ones mentioned), are those of Peter Apian in the 'Introductio Geographica.' &c., Ingoldstadt, 1533, folio. They are minute-tables to a radius of 100,000, and were reprinted the next year in the same author's 'Instrumentum primi Mobilis,' Nürnberg, 1534, folio. Apian states that they are of his own calculation, and this is to us a strong presumption that no such tables had been previously printed; for Apian was a great reprinter of the writings of others at his own press, and very unlikely to have re-calculated any table which he knew to exist already. The statement that the work of Regiomontanus on triangles, Nürnberg, 1533, folio, contains tables of sines, is incorrect: we know it from examination of two perfect copies. We can point out how the mistake arose. Lalande (Bibl. Astron.) says that the first edition of the work, Basle, 1536, has in the title-page "una cum tabulis sinuum." Now the fact is that Lalande, who had only seen the second edition (*Basle*, no date, known to be of 1561), which *does* contain tables of sines, took the liberty of presuming that the first edition was the same in contents, title, and place; in all of which he was wrong, and in the date also.

In 1542 Rheticus, the most laborious of all the table-computers, made his first appearance as the editor of a work of Copernicus, 'De Lateribus et Angulis Triangulorum,' &c., Wittemberg, 4to (Weidler and Kastner). This contains a minute-table of sines to a radius of 10,000,000, being the first-published seven-figure table: the copy in the Libri sale of April, 1861, is the only one we ever saw. The table which appeared in the following year, in the great work of Copernicus [COPERNICUS, in BIOG. DIV.], is an abridgment of the preceding; going only to every ten minutes, and to a radius of 100,000.

In 1541 appeared one of the tables which have obtained most celebrity: being the 'Tractatus Geo. Purbachii super propositiones Ptolemæi de Sinubus et Chordis, item compositio Tabularum Sinuum per Joannem de Regiomonte. Adjectæ sunt Tabulæ Sinuum duplices per eundem Regiomontanum,' Nürnberg (1541), folio (Kastner, &c.). The two tables of sines are both minute-tables, with radii of 6,000,000 and of 10,000,000. The table of tangents to every degree is repeated again under the name of *tabula fœcunda*. In a mixture of tracts by Regiomontanus, Walther, Schoner, and Purbach, headed 'Scripta . . . de Torqueto, Astrolabio Armillari, . . .' Nürnberg, 1544, 4to, is a table by Purbach, called *Tabula Gnomonica*, which is a table of tangents to the radius 1200, giving the angle to each unit of the 1200. This table is repeated in Gemma Frisius, 'De Radio Astronomico,' Antwerp, 1545, 4to, already mentioned.

Rheticus, in the meanwhile, was pursuing the route of analogy, which suggested to him the formation of a table giving *all* the ratios which exist between the sides of a right-angled triangle; by which he was led to the invention of what were afterwards called secants, to the completion of the trigonometrical canon, and to its arrangement in the form which it has ever since preserved. His rights in this matter have long been forgotten; and it is only recently that the work which established them has received any notice in modern times. (See the Notices of the Astron. Soc., vol. vi., p. 213, and Phil. Mag., June, 1845.) In 1551, the year following that in which he was placed in the 'Index' as a forbidden author, he published his 'Canon Doctrinæ Triangulorum,' Leipzig, 4to. This is a complete canon to every ten minutes, and to a radius of 10,000,000 (or, as we should now say, to seven decimals) with differences, so arranged that the matters connected with each angle also belong to its complement, in the manner so familiar to those who can use any modern table. This arrangement may be called *semi-quadrantal*, as opposed to the older *quadrantal* arrangement in which the sines are carried direct from 0 to 90°. Accordingly, the page of Rheticus has both a head and foot description, as in modern tables. So completely is he bent on the idea of a register of the proportions of right-angled triangles, that he rejects the use of the word sine. In the place of the sine and cosine he has the perpendicular and base to an hypothenuse of 10,000,000; for what were afterwards called the tangent and secant he has the perpendicular and hypothenuse to a base of 10,000,000; for the cotangent and cosecant he has the base and hypothenuse to a perpendicular of 10,000,000. The same description is adopted in his larger work, of which we shall presently speak. To the smaller work is appended a dialogue, which introduced Rheticus to his future editor; for Valentine Otho was so struck by it, that he went to Hungary to obtain information on the subject from the author. Otho relates that in the first interview, when he had hardly stated his purpose, Rheticus interrupted him with, "You are just as old as I was when I went on the same errand to Copernicus."

In 1554 Erasmus Reinhold (who had been the colleague of Rheticus[*] in teaching mathematics at Wittemberg) published the 'Primus Liber Tabularum Directionum,' Tübingen, 4to. In this work, for the first time, occurs a *canon fœcundus* (not yet called a table of tangents) carried to every minute. Both sines and tangents were computed to a radius of 10,000,000, and have differences. By the complemental degrees at the bottom of the pages, it appears that cosines and cotangents were intended. This work of Reinhold, though founded upon Regiomontanus, must not be confounded with his professed edition of the 'Tabulæ Directionum' of Regiomontanus himself, which had tangents only to every degree, and was printed several times, the last edition being in (1606). (We have not thought it worth while to catalogue all reprints.)

In (1558) (Delambre) Maurolycus published his edition of Theodosius, Menelaus, &c. (Messina, 4to), containing the three tables, that of sines, the *tabula fœcunda*, and the *tabula benefica* (as he called the present table of secants). This table goes only to degrees (except that tangents and secants are given for 15, 30, 45, 55, and 59 minutes of the last degree of the quadrant), and is to a radius of 100,000. Delambre, &c., suppose that these are the first tables of secants which were published, and they accordingly attribute the invention to Maurolycus. But we have seen that it is due to Rheticus; and Finck (presently mentioned), who lived close to these times, states expressly that Maurolycus borrowed this table from Rheticus.

In 1562 a pupil of Rheticus published a table of sines to every minute, and to a radius of 10,000,000, with differences for one second. This was Samuel Eisenmenger (or Siderocrates, as he wrote himself), in his 'Libellus Geographicus,' Tübingen, 4to. And there was, as we find stated in various quarters, a table of sines in the work on dialling of Hermann Witekind, 'Conformatio Horologiorum,' of which the first edition is said to be of Heidelberg (1576), 4to. Blundeville says they are to a radius of 100,000.

The first complete canon *to every minute* (that of Rheticus in 1551 being to every ten minutes) was Vieta's 'Canon Mathematicus, seu ad Triangula, cum Adpendicibus,' Lutetiæ, apud Johannem Mettayer, &c., 1579; to which is annexed, with a new title-page, 'Francisci Vietæi universalium Inspectionum ad Canonem Mathematicum liber singularis, Lutetiæ,' &c., as before.

This same book, from the same types, is also found with another title-page, as follows:—'Francisci Vietæi opera mathematica, in quibus tractatur canon mathematicus, seu ad triangula: item Canonion, &c., &c., &c., Londini, apud Franciscum Bouvier, 1589.' This publisher is not mentioned by Ames.

---

[*] It would be better if we knew precisely *when* it is good. Not to believe more than half is a very proper caution: but there arises the old difficulty, Which half!

[*] Reinhold taught the higher branches, and Rheticus the lower. It is very illustrative of the neglect into which the prohibition (with other circumstances afterwards noted) caused the writings of Rheticus to fall, that Weidler—himself of the university of Wittemberg, writing and printing his History of Astronomy there, giving minutely the dates of Rheticus's degrees from the *matricula* or register, and stating that from the time when he and Reinhold were colleagues it had always been customary to have two teachers of mathematics—is as ill-informed as any one about the writings of Rheticus, and in particular knows nothing of the publication of 1551, of which we may therefore be pretty sure there was not a copy in the library.

The same book, again from the same types, is in the British Museum with a third title-page, as follows:—'Fran. Vietæi Libellorum Supplicum in Regia magistri, insignis que Mathematici, varia opera mathematica: in quibus tractatur Canon Mathematicus, seu ad triangula; item Canonion, &c., Parisiis, apud Bartholomæum Macæum,' &c., 1609.

That the second and third are really the same book as the first, with a new title-page, we have ascertained by carefully comparing various words which are mis-spelt, and letters and lines which are broken, in all three: also by the fact that the second title-page, 'Francisci Vietæi,' &c., exists, date and all, in the second. In the third, the second title-page is taken out, and Mettayer's address is printed after the first. This book was, from its extreme scarceness, a bibliographical curiosity; we have repeatedly examined five copies, three with the first title-page, one with the second, and one with the third: in two of the first three, some figures which are not found in the third have been stamped in after the printing; and the same stamping is apparent both in the fourth and fifth. The *canon mathematicus* is the first table in which sines and cosines, tangents and cotangents, secants and cosecants, are completely given: they are arranged in the modern form, in which each number entered has a double appellation. But the notation of decimal fractions not being invented, the mode of description is as follows:—to give the sine and cosine of 24° 2′, Vieta states that the hypothenuse being 100,000, the perpendicular and base are 40,727 and 91,330 9; and in a similar way for the others: and here it is remarkable that in the cosines Vieta does use a species of decimal notation, leaving a blank space instead of using a decimal point; for, to an hypothenuse 100,000, the base to an angle of 24° 2′ is what we should now write 91330·9. There is also a large collection of rational-sided right-angled triangles, which form a trigonometrical canon, but not ascending by equal angles. The work concludes with a copious collection of trigonometrical formulæ and various numerical calculations, for mention of which see Hutton's 'History of Trigonometrical Tables,' prefixed to his logarithms, and inserted in his tracts. A short preface by Mettayer, prefixed to the 'Universalium Inspectionum,' &c., states that Vieta found great difficulties in getting tables printed at all, and also that plagiarists had printed and sold something of the kind, but what is not stated. Vieta himself (Schooten, p. 323) calls this book *infeliciter editus*, and hopes that a second edition will be of better authority.

Besides the three title-pages above mentioned, there must have been a fourth; for in the title of that which Delambre examined was the motto *Dura et quiesce*, which certainly was not in either of the three seen by us. The work has well obeyed the direction given: it has lasted in silence, having never been described in catalogues or histories till modern times. Copies seem to have been rare in Germany; neither Weidler, Heilbronner, nor Kastner mentions it. Hutton never saw but his own copy; Montucla (in France!) never saw more than two—one in the royal library, and one sold at the Soubise sale (but it is not in the catalogue of that sale), which the historian would fain have bought, had not a *curieux* bid too high. And this was only by the time Montucla's second edition was written, for by the mention of it made in the first edition it is clear that the author had never seen it. We have examined in London at least eight copies. We have mentioned the complaints which the author had to make against the printers: Montucla states that Vieta bought in as many copies as he could. There are several signs of something odd having taken place in the printing; and the following is worth mention:—To one of the copies we have seen (as well as to one of those in the Museum) is appended one folio sheet, in correction of a mass of errors in one sheet of the collection of formulæ: this sheet is a separate publication, with the date, 1579, and printer's name on it (J. Mettayer).

Vieta imitates Rheticus in his method of heading the tables, but in addition uses the word sine, and calls the table of tangents *fœcunda*, and that of secants *fœcundissima*. He complains that elegant names have not been found, and states that he gets his denominations from certain *Rhapsodi* (as he calls them; it is not often that mathematical tabulators are called rhapsodists), whom he does not name. In a later work, the 'Responsa,' &c. [VIETA, in BIOG. DIV.], published in 1593, he names and objects to the words tangent and secant, which by that time he had seen. And he proposes to call the tangents *prosines* or *amsines*, and the secants *transsinuous* lines.

As to the matter of Vieta's tables, it is worth notice that they must have been made by independent calculation. They do not exhibit the errors in the last tangents and secants which appear in all writings prior to the more correct publication of Rheticus by Pitiscus. On the additions made by Vieta to the theory of trigonometry we have not here to speak: but we may simply say that they made the computation of a trigonometrical canon a much easier thing than it had theretofore been. Delambre is quite right when he observes that the 'Trigonometria *Britannica*' of Briggs is altogether French in all that relates to the non logarithmic part of it. Had he known a little more of Vieta, he could have reinforced his assertion. For Briggs's method of solving equations which Delambre (evidently not understanding it) describes as an obscure mixture of division and extraction of roots, was the slightly amended form of Vieta's numerical exegesis, to which we have referred in INVOLUTION AND EVOLUTION. And as, by Gellibrand's account, we trace the commencement of Briggs's labours to shortly after the time when Vieta first published this exegesis, it is by no means an unlikely conclusion that the power of trisection and quinquisection given by this mode of solving equations first put it into his head to construct the table. [INVOLUTION AND EVOLUTION.]

Purbach and Regiomontanus had seen the advantage of adopting decimal tables, though their use of the radius 600, &c., was a remnant of sexagesimalism. It was reserved for Maurice Bressius to show himself a century behind his time, by publishing in his 'Metrices Astronomicæ Libri Quatuor,' Paris, 1581, folio, sexagesimal tables to every minute of sines, tangents, and secants, or as he calls them, *sines*, *adscripts*, and *hypothenuses*. Thus, the radius being 60°, the sine of 57° 20′ is given as 50° 30′ 34″; and the adscript and hypothenuse as 1 sex. 33° 34′ 46″, and 1 sex. 51° 9′ 44″; 1 sex. meaning 60°. Accustomed as we are to look upon sexagesimal division as sacred to angular and horary measure, we are apt to forget that the time was when other subdivisions were rarely used in Europe.

As yet we do not find the modern names of *tangent* and *secant*. These were introduced in 1583 by a young man of twenty-two years, Thomas Finck, of Flensborg in Denmark (who died in 1656, aged 95), in his 'Geometriæ Rotundi [sic] Liber XIV.,' Basle, 4to. His part in the matter was quite forgotten, and has been recently revived (see Phil. Mag., May, 1845). He introduces the words with expressions which cannot * be interpreted otherwise than as a proposal of his own, to which it must be added that no earlier use of these words has ever been brought forward. The tables of sines, tangents, and secants, so called, which Finck has introduced in his work, are to every minute, and to a radius of 10,000,000. Finck deserves a much higher name than he has got, for the contents of this work alone: there are other writings of his, which we have not seen. He calculated his own secants by a theorem which answers to the formulas

$$\text{Sec}\,\theta = \tan\theta + \tan\left(45^\circ - \frac{\theta}{2}\right).$$

In (1585–6) Clavius published at Rome, in quarto, his edition of Theodosius, to which is appended a treatise on triangles, and a table of sines, tangents, and secants, under those names to a radius of 10,000,000. They were reprinted in the folio collection of his works, Mayence, 1611; and the table of sines only in his 'Astrolabium,' Rome, 1593, 4to. It is clear, on inspection, that these tables are, so far as tangents and secants are concerned, a reprint of those of Finck, in their preliminary theorems, in their arrangement, in their omissions, and in their errors, as well as in the new terms with which they are headed. The name of Finck is suppressed as well as that of Rheticus; both of them were Protestants, and Clavius was a Jesuit, high in favour at Rome. Delambre expresses his astonishment that Clavius, in recapitulating the names of celebrated writers on dialling, should have omitted Sebastian Munster. The fact was that Munster followed Luther. We are not quite certain that a greater than Clavius was altogether exempt from this laughable weakness. When Vieta suppresses the names of his authorities, as above noted, calling them merely *rhapsodists*, we may almost suspect that he wanted to avoid speaking of Rheticus and Reinhold; for he was very intolerant.

In (1591) Philip Lansberg published 'Triangulorum Geometriæ Libri Quatuor,' Leyden, 4to, the first work known to Hutton in which the words *tangent* and *secant* are used; and in 1592 Magini published 'De Planis Triangulis Liber Unicus,' Venice, 4to. Both these contain full tables, taken from Clavius; and Magini is said to have repeated them in his 'Primum Mobile,' Bologna and Venice (1609). Magini, who goes beyond Clavius in historical reference, wilfully suppresses the name of Finck.

We at first thought ourselves unable to give a date to the tables of Stevinus, except within a few years, and conjecturally. That he published his Arithmetic in 1585, and that Snell † collected many of his works in Latin in 1605–8, are the facts which are supposed to mark out the known limits of his career. The tables must have been published after 1593, since Vieta's names for the tangent and secant are mentioned; probably long after, for Vieta's works were of very slow travel. We ourselves believe fully that the Cosmographia, which contains the tables, was never published until it appeared in what is called Snell's collection (in 1608). These tables are to every minute, to a radius of 10,000,000, and they are copies of Finck, Clavius, &c. Recent researches in Belgium have made it appear that Stevinus was

* "Erit AI tangens .... Sic vocare placuit [*i. e.*, nobis] quia .... Damus aliquid .... Regiomontano .... damus etiam aliquid receptæ consuetudini. Verum id non facile damus ut verba ea in usu retineamus quibus elegantiora, breviora, significantiora, veriora habeamus." And again; "Sequitur .... quæ vulgo canon fæcundus, nobis canon tangentium dicitur: et canon hypotenusarum Rhetico, nobis canon secantium vocatur."

† It can be made very obvious that Stevinus *was alive* throughout the whole of the printing of these two volumes (or five volumes bound in two). In the very *last page* of the *last volume* (index excepted), the author excuses himself for not fulfilling certain announcements, because he had not made up his mind about the subjects of them, and the printer could not wait. And this after referring to the places of the several matters in the very volumes which are supposed to be the collection of the editor. Besides, Snell, the reputed editor, was only seventeen years old when the work was published.

born in 1548, and died in 1620, which puts our opinion beyond dispute. The mistake about Snell seems to have originated with Gerard Vossius.

In (1588) Nic. Raymar, Ursus Dithmarsus, published 'Fundamentum Astronomicum, id est nova Doctrina Sinuum,' &c., Strasburg. We cannot make out from the descriptions, whether this work contains tables or not. If Kastner's and Delambre's descriptions be complete, it did not.

Who published the first English trigonometrical table is a point which we have never seen examined: and we must investigate it in the best way we can from rather scanty materials. We cannot find the word *sine* mentioned in the works of Recorde, nor in the English works of either Digges, father or son, nor in those of John Dee; nor indeed in any work written in English before Blundeville, except that of Burroughs presently cited. In the 'Alæ, seu Scalæ Mathematicæ' of Thomas Digges, London, 1573, 4to, trigonometrical processes are required for which allusion is made to Copernicus and Regiomontanus, and the tables of Rheticus are often cited (the ten-minute canon, of 1551). In John Dee's 'Parallacticæ Commentationis Praxeosque Nucleus quidam,' London, 1573, 4to, there are also solutions of triangles, and the tables referred to are those of Regiomontanus with the radius 60,000, before mentioned. But neither of these writers makes the smallest allusion to any tables published in England. We have examined the libraries of more than one diligent collector of English works of the 16th century, without finding anything which at all controverts our decided impression that Blundeville[*] was the real introducer of a complete canon of sines, tangents, and secants.

Blundeville's 'Exercises,' London (1594), 4to (it is said sometimes that 1597 is the date of the first edition, but incorrectly; the fourth is of 1613), were commenced, as he informs us, about seven years before. He alludes to Regiomontanus, Copernicus, and Clavius, from whom he took his tables. And he informs us that Regiomontanus is in folio, and that Clavius is in quarto, and published in 1586, at Rome. We rely much on this in our conclusion that his were the first tables: for to mention the form of a book, or the date of publication, is very rare with the writers of his time; and it is most likely that so precise a person would have noticed any previous work of the same kind in his own country. The tables, being copies of Clavius, have already been described. These 'Exercises' went through seven editions at least: the seventh, now before us, has the tables corrected from Pitiscus, by Robert Hartwell, the editor; it is London, 1636, 4to.

It must be noticed, however, that though Blundeville gave the first English canon complete, a table of sines *only* had been printed four years before. It is at the end of the 'Horologiographia, the art of Dialling,' by Thomas Fale, London, 1593, 4to (reprinted[†] in 1652). The sines are to minutes with a radius of 100,000. This then is the earliest table, but it is of sines only. We have seen that Digges used sines, but he is a Latin writer, and refers to a foreign table. Perhaps the first writer who *used* them in English (but still with foreign tables) is the well-known W. Burroughs, in his 'Discourse on the Variations of the Compasse,' published in (1581). In the preface he apologises for introducing rules "wrought by the doctrine of signes and triangles, which may seem strange in our English-Tongue," and all he gives on tables is in the following passage:—"In these examples I have used the abridged table of 100,000 the whole sine, which though it give some ease in the working, yet it is not so exact as that of 10,000,000 of *Erasmus Reinholdus.* Unto the which, with his *Canon fæcundus*, answerable to the same, if the third *Canon* of the *Hypthenusæs* were annexed, wee should have an entire Table for the Doctrine of Triangles, that might worthily bee called *The Table of Tables.* Which thing, though *Georgius Joachimus Rheticus* have well begunne, and framed it orderly, from ten Minutes to ten: yet is it left very rawly, for such as desire the exact truth of things. I have therefore for mine owne ease and use, Calculated the complement of this Table, and almoste ended it, for the whole Quadrant, from minute to minute: which if in the mean time before I have finished, I shall not finde it extant by any other, I will publish it for the commoditie of all such as shall have occasion to use the same for navigation and cosmographie." But this table was never published, and accordingly the editor of the edition of 1614 refers the reader to Ralph Handson's translation of Pitiscus, and the very tables of that work are annexed to the end of some copies at least of the edition of 1614. They are tables to every minute, and to a radius of 100,000. The table is semi-quadrantal, and the complementals are joined in contiguous columns, without any heading by which further than 45° could be guessed at. We cannot describe the first edition of Handson's work, having only seen the second, which is London, 1630, 4to; at least the *tables* are so dated, though the *work* has no date. (Wilson, in the preface to his Navigation, says the first was in 1614.) In 1609, John Speidel, afterwards well known in the history of logarithms, began his career by publishing, in quarto, 'Certaine verie necessarie and profitable Tables; namely, A Table of Sines, Tangents, and Secants, &c.' This tract of sixteen pages contains a canon to every ten minutes, and to a radius 1000, with some tables subsidiary to astronomy.

In 1610, Arthur Hopton published 'Baculum Geodæticum sive Viaticum, or the Geodæticall Staffe,' London, 4to. The seventh book of this is called 'Trigonometria, containing Longimetria, and Altimetria, performed by Synnicall supputation, with a Canon for the Dimension of tryangles.' The canon (from Pitiscus) is complete for every five minutes and to a radius of 100,000. Peculiar to this table is a heading by which the sine, tangent, secant of the complement, or defect from 90°, are also made to belong to the excess above 90°; thus at 10° the sine, tangent, and secant of 80° are made to be those of 100°.

The history of the rest of the works of Rheticus was, till lately, very inaccurately told, and there is still some confusion about it. After Rheticus had published his ten-minute canon, already noticed, in 1551, he was occupied till his death in 1576, in what is, beyond a doubt, the most laborious work of calculation that any one man ever undertook: a complete trigonometrical canon to every ten seconds, and to ten places of decimals, sines to every ten seconds, and to fifteen decimals, with the first and last degree to every second, and tangents and secants to every minute, and to fifteen decimals. It is to be remembered that he wanted the abbreviations which might have been introduced, if he had known what Vieta had done. At his death, he had finished this work, within a mere trifle: what little remained to do, was done by his pupil Valentine Otho, and part of it was published at Neustadt[*] in the Palatinate, 1596, in folio (sometimes bound in two volumes, from its thickness). The title of the book, which was published at the expense of the Emperor Maximilian, is 'Opus Palatinum de Triangulis a Georgio Joachimo Rhetico cœptum: L. Valentinus Otho Principis Palatina Frederici IV. Electoris Mathematicus consummavit.' The contents are (after prefaces) three books *de Fabrica Canonis*, on the construction of the Canon, by Rheticus; one book on plane triangles, and four books on *right-angled* spherical triangles, by the same; five books on oblique-angled spherical triangles by the editor, Otho; three subsidiary astronomical tables called *meteoroscopia;* the great table, in 540 folio pages, giving, under the titles already described, the sines, tangents, and secants, for every ten seconds, with a radius of 10,000,000,000, or, as we should now say, to ten places of decimals; a list of errata; and lastly, a second table of cotangents and cosecants for the first half of the quadrant, to every ten seconds as before, and to a radius of 10,000,000. The appearance of the last table is merely the editor's want of judgment; it is clearly nothing but a previous attempt, made before the larger plan was resolved on, and is much less accurate than the great table to ten places.

Within a short time after the 'Opus Palatinum' was published, it was found (by whom or how we are not told) that the tangents and secants towards the end of the quadrant became more and more erroneous, and at the extreme end were very erroneous indeed. All persons who know anything of trigonometry are aware that, to calculate the tangent or secant of an angle near to 90° true to any number of decimal places requires that the cosine should be calculated to a greater number of places. Rheticus seems to have foreseen this, and to have provided sines true to a larger number of places than those which were published. When the defect was discovered, the advisers of the Elector Palatine, Frederick IV., to whom the work was dedicated by Otho, caused him to intrust the superintendence of the corrections to Bartholomew Pitiscus of Grünenberg, in Silesia, who had been his own teacher, and who was still in his service as chaplain: we suppose this means that Pitiscus himself was the adviser. Pitiscus applied to Otho, then an old man, for the larger tables of sines which Rheticus was known to have calculated: Otho was never able to find them; but at his death they were found among his papers. Pitiscus accordingly made *two* publications; but so confused are the statements respecting them, that some of our readers may almost doubt the fact. These two publications were as follows: 1. He corrected all that part of the great table of the 'Opus Palatinum' in which the tangents and secants are sensibly erroneous, being the first 86 pages. These he reprinted, and joined his reprint to the 540—86, or 454 remaining pages of the great table. He then cut away all the *Fabrica Canonis*, the books on triangles, the *Meteoroscopia*, and the small table of cotangents, &c., and added to his own 86 pages and Otho's 454 a short description, or *commonefactio*, as he calls it. This of course gives a thin folio. But we collect from Delambre's account of Prony's copy, that besides this, there were such things as complete copies of the 'Opus Palatinum,' with the 86 correct pages substituted for the incorrect ones. And we presume that to these the separate title of the *commonefactio* was not appended, being printed only for the separated table. For Prony, Delambre, and all the rest of the French savans (to whom the subject was particularly interesting, on account of its connection with the 'Tables du Cadastre,' then preparing) missed the date of the correction, which nevertheless appears on the separate title-page of the *commone-*

---

[*] This is the same as the Blundeville who wrote on Horsemanship. In 1846, a patent for a horseshoe was upset in Chancery, upon proof that Blundeville had described it before 1600.

[†] That is to say, furnished with a new title-page: beyond a doubt the type is of the previous century. This, we find, was not an uncommon practice in the middle of the 17th century, in England. We suppose that the civil troubles, which operated against the production of all but theology or politics, threw the booksellers back on their old stocks, which they then replaced with new title-pages, defacing the 17th century with some of the worst specimens of the irregular black letter of the 16th.

[*] Weidler, copied by Montucla, gives Heidelberg, 1594; and Lalande reconciles them with fact by taking *Neostadium* to be Latin for Heidelberg! The Neustadt here mentioned is now part of Bavaria, lat. 49°+, long. 11°−.

factio. The person who is used to accurate descriptions of books might possibly, without this warning, throw away the thin folio we are speaking of, under the idea that it could not be in any sense an edition of the Opus Palatinum: which in fact it is not, though it is an edition of all that was corrected. The 86 pages of reprint are easily distinguishable by the inferiority of paper and type.* The title-page of the thin book is a sort of fly-title, without date, &c., on the first page as follows:—'Georgii Joachimi Rhetici magnus canon doctrinæ triangulorum ad decades secundorum scrupulorum, et ad partes 1 0000 00000. Recens emendatus a Bartholomæo Pitisco Silesio. . . . Addita est brevis commonefactio de fabrica et usu hujus Canonis. . . . . Canon hic, una cum brevi commonefactione . . . . . etiam separatim ab opere Palatino venditur. In bibliopoleio Harnischiano.' And the *commonefactio* has a title-page of its own, as follows: 'Bartholomæi Pitisci Grunbergensis Silesii Brevis et Perspicua commonefactio de fabrica et usu magni canonis doctrinæ triangulorum Georgii Joachimi Rhetici. Neostadii Typis Nicolai Schrammii MDCVII.' It thus appears that the date is 1607, which no one has yet noted, except Kastner, copying an older description, apparently without any distinct separate knowledge of what he was describing. 2. Pitiscus published, Frankfort, 1613 (misprinted on two of the titles 1513, by omission of a C), folio, the tables of Rheticus by which himself was enabled to make the preceding corrections, under a long descriptive title beginning with 'Thesaurus Mathematicus.'† The contents, described in modern language, are:—sines to every ten seconds and to fifteen decimals, with first, second, third, and sometimes more differences; those of the first and last degrees, also to fifteen places, and to every second: the fundamental sines, from which the rest were calculated, to twenty places: the sines of every 10th, 30th, and 50th second in the first 35 minutes to 22 places (this last table was done by Pitiscus himself). Pitiscus died in July, 1613, very shortly after the publication of the Thesaurus.

When we come to reflect, we find that the tables of Rheticus did not make such an epoch in the history of these things as might have been expected. The ten-minute canon, 1551, which we have described, and of which the memory was almost lost, introduced the secants, completed the system, and suggested to Vieta both the extension and its form. Had Rheticus published his own large table before his death, in 1576, it might have been otherwise: but deferred as this publication was, partly till 1596, seventeen years after Vieta's Canon had appeared, and partly till 1613, the year before the publication of logarithms it turned out that the impulse had already been given from other quarters. The next great tables of sines which were produced were the work of Briggs, who was, as we have seen, exclusively the follower of Vieta in this part of the matter. The labours of Rheticus became little more than a tradition, though Vlacq used the last half of his quadrant in the construction of logarithmic sines. Vossius, 1650, knew nothing definite of the tables except the Thesaurus, and that only in time to insert it in the additions to his work. Sherburne, 1675, has not a word of tables. Briggs hardly mentions Rheticus; his biographers not at all. The Jesuit Blancanus omits him as a condemned writer; and it is to be noticed that he was, as to this matter, worse off than Copernicus himself; for he was *damnatus auctor*, Copernicus only *damnati libri auctor*: and the absolute prohibition against all his writings must have tended to the oblivion into which his name fell. Weidler, 1741, writing in the University of Wittemberg, in which Rheticus taught, had not seen the Opus Palatinum, and knew nothing of what Pitiscus had done. In the Berlin Memoirs for 1786, John Bernoulli (the younger) revived the knowledge of the 'Opus Palatinum' and the 'Thesaurus;' and Lalande had previously come at some statement to the effect that Pitiscus had once received instructions to correct the former. But Bernoulli knew nothing of these corrections, and nothing was known until chance threw a copy of the corrected Opus Palatinum into the hands of Prony, who described it in a paper printed in the fifth volume of the Memoirs of the Institute, 1804. Delambre gave an accurate account at the beginning of the second volume of the 'Histoire de l'Astronomie Moderne.' Montucla had given nothing but mistakes. Hutton knew as much as Bernoulli. Kastner (1796, who would have got much more credit if he had given a proper name to his valuable work of bibliography, instead of calling it a history of mathematics) has a detailed account of all the matter, except the corrections of the Opus Palatinum, on which he could only quote from a periodical of 1789.

In (1599) Pitiscus published his own work on Trigonometry, with tables, generally to seven places, and having intervals which may be described, as presently noted, by 0 (1") 1' (2") 10' (10") 1° (1') 45°. The edition of 1608, now before us, has of course the corrected tangents and secants. It was reprinted again in (1612), and Dechales mentions a reprint, by Henrion, in (1623).

Pitiscus will always be remarkable as the priest who wished that all his brethren were mathematicians,* to make them manageable and benevolent.

Among the non-logarithmic tables, which were published after the invention of Napier turned all the calculators another way, was that of Schooten, 'Tabulæ Sinuum,' &c., Amsterdam, 1627, a complete canon to seven places, in a pocket volume with pages of two inches by four. It is often said to contain no error; but we believe the author's own assertion in the preface is the source of this opinion: Hutton found many errors in the last figures. There were two *principes* editions, one with explanations in Latin, the other in Dutch. Lipenius says this was reprinted in (1638?) and we know there is an edition of (1672) at Rouen, and of 1683 at Brussels. Editions are mentioned of (1640) and (1664), and also a Spanish edition, Brussels (1683), and of 1683 at Amsterdam, from different type. Joh. Meyer's tables, Strasburg (1619), contain sines, tangents and secants, squares, and cubes. Those of Adrian Metius (1633) give a complete canon, to minutes, to seven decimals. In (1627) Snell published his 'Doctrina triangulorum canonica,' Leyden, containing a complete canon to every minute, and to seven places. Cruger's 'Synopsis Trigonometriæ,' Danzig (1612), gave a five-decimal canon to minutes. Albert Girard's 'Tables des sinus,' &c., Hague 1627, are to five decimals; there was a Dutch reprint in (1629). Adrian Romanus gave tables (Delambre, 'Astr. Mod.,' vol. ii. p. 35) in (1609); they were taken from Clavius. The greater part of the contents of this paragraph are taken from different sources, and not from the books themselves. We might mention some anonymous tables from various catalogues, but anonymous works of this kind are so rare that we always suspect them. One, however, now before us, deserves mention. It is a thin quarto, Wurtzburg (Herbipolis), 1625, announced as intended for the students of the University. It contains a semi-quadrantal table of sines (only), and is entitled 'Canon sinuum ad decempedam accomodatus.' The table is to a radius of 10,000, but the four places of each sine are severally called radii, pedes, digiti, grana; and are so headed in every column. The degree is divided into 12 parts, each of which is called a *minute.*

Alsted's 'Encyclopædia,' 1649, the earliest work which has bulk enough to be compared with modern works of the same name, gives nothing more than a canon to degrees and seven decimals, with another to ten minutes and five decimals. The name only of logarithms is mentioned, and an insufficient definition given.

§ 6. *Tables of Logarithms.*—Before we enter on this subject we shall give a hint which may be worth the attention of future compilers, though in joining together two articles of older date than the additions we have not been able to take advantage of it to any great extent. Systems of tables may be arranged and spoken of either by their *sources* or by their *forms.* Thus in thinking of old books of logarithms we may have to ask whether they came from Vlacq or direct from Briggs; we also want to know the number of figures, the arrangement, &c. The tables of logarithms might with some trouble be divided into sets, those in each set being lineal descendants of their predecessors.

Our mention of different works will be found, as to length and minuteness, much out of proportion to their celebrity, in many cases: this cannot be avoided when we have information to give which is not commonly found.

1614. Napier, 'Mirifici Logarithmorum Canonis Descriptio, Ejusque usus, in utraque Trigonometria, ut etiam in omni Logistica Mathematica, Amplissimi, Facillimi, et expeditissimi explicatio. Authore ac Inventore, Ioanne Nepero, Barone Merchistonii, &c. Scoto. Edinburgi, Ex officinâ Andreæ Hart, Bibliopôlæ, CIↃ.DC.XIV.' 4to. Sines and Naperian logarithms of sines and tangents, to every minute and seven decimals.

It must be specially noted that the logarithms which Napier himself published are not precisely those which are now called Naperian; that is, they are not the simple logarithms to the base $\epsilon = 2{\cdot}7182818\ldots$ As the sines increase, his logarithms decrease. As he uses no decimal point, both his sines and logarithms are integers, the former to a radius of 10 millions. And if N be a sine and L the logarithm of it, as they stand in Napier, the equation connecting them is

$$N = 10{,}000{,}000\,\epsilon^{-\frac{L}{10{,}000{,}000}}$$

---

* The corrected copies of the work, thick or thin, may be distinguished from the uncorrected ones in a moment, as follows: Look at the bottom of page 7, at the running titles of the columns. The uncorrected copy will have, as it ought to have,

Basis Differentia Hypothenusa.

But the *corrected* copy (*quis custodiet ipsos custodes?*) will have, as it ought *not* to have,

Hypothenusa Differentia Basis.

† The copies of the two works, the 'Opus Palatinum,' and the 'Thesaurus,' which belonged to Delambre, were bought at the sale of his books by Mr. Babbage. The copy of the 'Thesaurus' is curious: it once belonged to De Thou, and was bequeathed to Delambre by Lalande. It sold at the sale for 216 francs; the 'Opus Palatinum' for 60 francs. Mr. Babbage has also a copy of the corrected table (the thin volume). He informed us that, in 1828, Reuss, the librarian at Göttingen, and the indefatigable editor of the 'Repertorium Commentationum,' &c., the most complete digest of scientific transactions which exists, was altogether ignorant of the existence of any corrections of the Opus Palatinum. This is a truly singular instance of the slowness with which bibliographical information spreads.

* In his preface he says, "Mansuetudo autem, bone Deus, quantum et quam rarum est Theologorum ornamentum! Et quam optandum esset hoc seculo, omnes Theologos esse mathematicos, hoc est, homines tractabiles et mansuetos." Perhaps the union of the characters of divine and mathematician gives a peculiar right to speak well of the latter; for Barrow says, "Tenerrimæ frontis et stomachi robustissimi, aut si mavis, pudentissimum tædiique patientissimum genus hominum sunt mathematici." We accept the *si mavis*, for there is no saying how the moderns might translate the first epithets.

Delambre proposes to call them *Naperian* logarithms, and to restrict the term *hyperbolic* to the *modern Naperian* or ε logarithms: but custom has refused.

The reader may have some curiosity to see a specimen of the *tabula princeps*: we therefore subjoin three lines from the page having Gr. 37 at the top and Gr. 52 at the bottom. The form is semiquadrantal, and the *differentia* is the logarithm of the tangent.

		+	−			
37 min.	Sinus.	Logarithmi.	Differentiæ.	Logarithmi.	Sinus.	
0	6018150	5078050	2829544	2248506	7986355	60

2	6022796	5070334	2817441	2252893	7982852	58

This work of Napier was reprinted by Baron Maseres, in vol. vi. of the 'Scriptores Logarithmici.'

(1616.) Reprint of the above, by Edward Wright, to one figure less, with Napier's explanation translated into English, and preface by Briggs, London.

(1617.) Briggs, 'Logarithmorum Chilias Prima,' London. This is the first publication of logarithms on Briggs's system.

(1618.) Benjamin Ursinus, 'Cursus Mathematicus,' Cologne, contains Napier's Logarithms. For his 'Magnus Canon,' see 1624.

(1619.) John Speidell, 'New Logarithms.' A new arrangement of Napier's, but giving sines, tangents, and secants, with numbers also to 1000. These 'New Logarithmes' are the first *modern Naperian*, or *hyperbolic* logarithms. The second edition was in 1620, not 1627, as we stated (from others) before we had seen it. The reason of the mistake is that the 'Briefe Treatise of Sphæricall Triangles,' which is frequently prefixed, has 1627 on its title-page.

Taking decimals it stands thus:—If $m : n$ be the sine of an angle, and if λ represent the logarithm to the base ϵ, the *figures* of the Naperian logarithm are found in

$$\lambda n - \lambda m.$$

Thus, the sine of 19° 38′ is ·336, very nearly. And we have

$$\begin{aligned} \lambda\ 1000 &= 6{\cdot}9077552\ldots \\ \lambda\ 336 &= 5{\cdot}8171111\ldots \\ \hline & \ 1{\cdot}0906441 \end{aligned}$$

Napier has 10906448.

The figures of Speidell's logarithmic sine are found in

$$10 + \lambda m - \lambda n$$

thus for 19° 38′ he has 890936. But he leaves the 10 out of all the secants and the last half of the tangents. His logarithms of numbers, 0 (1) 1000, are modern hyperbolic to six decimals, as we should now say, but without the decimal point; thus at 770 he has 6646388 not 6.646388. To each logarithm he gives its difference, its arithmetical complement, and the halves of all three. Also an additional column which shows that he means to use his table in calculation by feet, inches, and quarters. Thus the number 775 has 16.1.3 opposite to it, there being 775 quarter inches in 16 feet 1 inch 3 quarters. At the bottom of each page he puts the logarithm of 100 and of 1000, for help in decimal fractions.

Speidell, as we have seen, first published in (1619); Baron Maseres reprinted from the "tenth impression," dated (1628); there was an edition in (1627); Hutton mentions the seventh, dated (1624); we have the fifth, dated 1623, and the sixth, dated 1624; the Royal Society has one of 1623; Murhard gives the third impression, of (1621), and we have the second, dated 1620. In his "briefe treatise" above mentioned, Speidell mentions, and naturally complains of, those[*] who had printed his work without an atom of alteration, and yet dispraised or undervalued it in their prefaces for want of alterations which themselves either could not or would not make. This he attributes to his not having been at Oxford or Cambridge.[†] Having kept our eye on this work until we have obtained four copies of it, though the British Museum[‡] does not possess one, without ever finding the smallest trace of any reproduction by another hand, we permit ourselves to doubt Speidell's assertion about the reprints: and the more readily after finding out the reasons for suspecting him of unfairness of which we shall presently speak.

Whether for his own reason or not, Speidell's name was very little known.[*] The Continental writers rarely mention him; Wallis knew nothing of him; and even his own son, Euclid Speidell, when he published his 'Logarithmotechnia,' in 1688, had no accurate information on his father's writings; for he says, "I do find my father printed several sorts of logarithms, but at last concluded that the decimal or Briggs's logarithms were the best sort for a standard logarithm, and did also print the same several ways." This must have been merely a mistaken tradition, arising from Speidell's not having printed the same logarithms as Napier: we may safely say he did not print any decimal logarithms. In addition to this testimony as to the rapid spread of logarithms in England which Speidell's circulation gives, we may state that their advantages were immediately seen by the practical mathematicians. Aaron Rathborne, in his 'Surveyor,' London, 1616, recommends the use of the "tables and more than admirable invention of logarithmes by that divine and noble writer the Lord Marchiston, whoes name and honour will never out."

It is to be noticed that two different tables of common logarithms accompanied Speidell's sines, &c. Our second, fifth, and one of two copies of the sixth, have, through 0 (1) 1000, the logarithm and its complement with the common difference between them, and, by the side of them, the semi-logarithm and semi-complement, with *their* common difference between them. But our other copy of the sixth impression has nothing but plain number and logarithm, without even the differences. And the larger table has, up to 960, an argument in shillings, pence, and farthings.

Thus far we had got in the revision of our former article, when we took it into our heads to compare the four copies before us, and, excepting only the new table of common logarithms in one of the *sixth* copies, we found them to be all from the same type, even to the very title-pages. It is true that one has 'The 2. Inpression. 1620,' and another 'The 6. Inpression. 1624,' &c.; but as much as 'The Inpression. 162 ' is from the same type in all. We cannot be deceived here, though those who are not used to such comparisons may think it possible. The inferior printing of that period abounds in badly formed, ill ranged, and blurred letters: and every instance of malformation is common to all our three cases. Hyphens, in particular, are very good tests: and one in "Ho-nourable" which happens to slant upwards in all three, and another in "Play-House" which happens to slant downwards, are hardly possible coincidences. Either the type was kept standing, and each year's sale was called an impression, or the title-page was several times fraudulently set forward in date after a number of copies had been taken off. There is no printer's name; and that the type should have been allowed to stand for many years is very unlikely, though we must see that the occurrence of an inferior table of common logarithms in the late editions is in favour of the supposition. It seems to favour the hypothesis that the forms of some of the last pages got broken up by accident, and that the inferior table was set up to replace them.

1619. Napier. 'Mirifici Logarithmorum Canonis Constructio,' Edinburgh, edited by Napier's son.

1620. Reprint of Napier, both the 'Descriptio' and the 'Constructio,' at Lyons, by Bartholomew Vincent, bookseller.

(1620). Gunter, 'Canon of Triangles,' first trigonometrical canon with Briggs's 'Logarithms.' We have not seen the first edition of this canon, which is semi-quadrantal, 0 (1′) 45° to seven decimals, and 0 (1) 1000 to eight. It was certainly first published in 1620, alone; and Wingate, in 1624, states it to be of Gunter's own calculation, and acknowledges it as the source of his own reprint. A year or two afterwards, the work on the cross-staff was published, to which this canon was attached: and in future editions the two always went together. The second edition of both was in 1636; the fourth (edited by Henry Bond, who perhaps edited the third, of which we know nothing) in (1662); the logarithms of numbers being 0 (1) 10,000 to seven decimals. Gunter is entitled to rank as one of the primary calculators of logarithms, with Napier, Briggs, John Speidell, and Vlacq.

(1620). J. B. [Justus Byrgius], 'Arithmetische und Geometrische progresse Tabulen,' Prague. This is the title given by Montucla, and the history of the book is as follows:—Kepler had stated that Byrge had invented the very same logarithms as Napier many years before the latter published anything on the subject. And Bramer, author of a German work on perspective, Cassel (1630), says that his brother-in-law and teacher, Justus Byrgius, had, twenty years before that time, made a table of progressions with differences of 10, calculated to nine figures, which he had published without text at Prague in 1620. This announcement obtained no notice, until Kästner informed Montucla

---

[*] To them he speaks as follows, in the introduction:—

> "To the M. C. Z.
> If that thou canst amend it,
> So shall the Arte increase:
> If thou canst not: commend it,
> Else, preethee hould thy peace."

[†] "Yet to satisfie in part the learned, that I can giue a reason for what I doe, I will set downe the making of these 2. last Theorems, whereby they may (if so they please) suppose I can doe as much for the rest, and whether some of them doe or no, I passe not greatly, for that they are sorry I can doe so well, not hauing seene one of the Vniuersities" (p. 27).

[‡] The British Museum is well supplied with mathematical works of the period: and the deficiency illustrates what we shall say on the decadence of J. Speidell and his works. It is very much to be regretted that the Museum did not purchase Dr. Hutton's library. The matter was in discussion, and almost in negotiation; but things were prevented from going further by Sir Joseph Banks. Hutton distinctly declared, both at the time of the sale and after, that his "old implacable enemy" had prevented the Museum from making the purchase, and that such was the frequent opinion of those who thought about such things. (Bruce, 'Life of Hutton,' Newcastle, 1823). Thus the finest set of mathematical tables ever collected in England was dispersed.

[*] There is not now a copy of any edition in the British Museum. Hutton happens to say that there is in the seventh impression (being the one he had before him) a table of logarithms of numbers. In the 'Encycl. Brit.' this is translated into an assertion that the logarithms of numbers were not added until the seventh impression.

(how, Montucla does not state; probably by private communication, or perhaps Montucla ought to have cited the 'Fortsetzung der Rechenkunst,' 1783) that this passage of Bramer had led him to look at some old tables which he had bought, and which had lain by neglected. And in these old tables he says he found the above work of Byrgius. This occurs in the second edition of Montucla's History, vol. ii. p. 10; see also Kästner's History, vol. ii. p. 375, and vol. iii. p. 14; and Delambre, 'Hist. de l'Ast. Mod.,' vol. i. pp. 560-566. It will be noticed that Byrgius did not publish till six years after Napier; so that in all probability Napier is first in point of invention as well as publication. Byrgius's system begins with 0 as a logarithm and 10^9 as a number; for every increase of the logarithm by 10, the number is multiplied by 1·0001; so that 10m has for its number $10^9\,(1{\cdot}0001)^{m-1}$. This is undoubtedly a rude table of logarithms, or rather of numbers to logarithms; and since Byrgius carried it up to 230270, the number to which is 999999999, he certainly secured the main advantages of logarithmic calculation.

Delambre, who has in general treated Napier with fairness, has in one instance formed a conclusion on premises so strange, that we hardly remember the like in any historian. ('Astr. Mod.,' i. 287-291.) Ursus Dithmarsus, the pupil of Byrgius, in his work of 1588 already mentioned, hints at some method by which he can calculate sines *even in numbers*, and *arithmetically*; and afterwards he talks of doing this in *common* numbers, by inscription, and in *logistic* numbers, by section of the angle. What he means Delambre cannot understand, neither, we should suppose, can any one else: but, seeing that he is a pupil of Byrgius, who afterwards made an antilogarithmic table, Delambre interprets him as possibly conveying the ideas of Byrgius to Napier. That is to say, certain unintelligible professions of Ursus, who does not even attribute them to Byrgius, and in which Delambre himself, with all his knowledge of logarithms, can neither see logarithms nor anything else, may have given the first idea of logarithms to Napier, or may furnish presumption that Byrgius gave that idea in some other way. One would really almost suppose that Delambre had been misled by the antithesis of *common* and *logistic* numbers, the usual terms of the day for integers and fractions. Thus, Kepler begins the Rudolphin tables by a chapter on the *logistics* he means to use, and warns the *logista* that he will express the distances of the planets by dividing that of the earth and sun into 100,000 parts.

The following is a summary of the ground of presumption that Napier's system was well advanced, in thought at least, if not in actual calculation, before 1588. Kepler testifies that Napier gave Tycho Brahé strong hints of what was coming in 1594. Now in 1593 Napier published the first edition of his interpretation of the Apocalypse; and there is no reason to doubt his declaration that he considered this as the main business of his life, and mathematics as only secondary. This heavy work shows what was his main employment in the years preceding 1594, in which year his system was well advanced: which we take to make probable, all things put together, that it was well advanced at least four or five years earlier. Napier returned from travel and settled down to study in 1571, and probably he soon began his researches. It is to be noticed that his system of logarithms did not stand alone. He informs us that he tried many plans to facilitate calculation, some of which might perhaps be published: this he says in the preface to his canon of logarithms. Accordingly, in 1617, the 'Rabdologia' appeared [NAPIER'S BONES]; and this was only one of three plans, of which the others are but named. Napier was not in haste to publish. His son informs us that the second tract, the 'Constructio,' was written years before the name *logarithm* was invented; and this description must have followed the actual calculation of much, if not all, of the canon.

1624. Briggs, 'Arithmetica Logarithmica,' London. Logarithms (decimal) to fifteen places, from 0 to 20,000, and from 90,000 to 100,000, with interscript differences. After his death, in 1631, a reprint was, it is said, made by one George Miller; the Latin title and explanatory parts were replaced by English ones; 'Logarithmicall Arithmetike,' &c. We must doubt the reprint of the tables, and think that they were Briggs's own tables, with an English explanation prefixed in place of the Latin one. Wilson (in his History of Navigation, prefixed to the third edition of Robertson) says that some copies of Vlacq, of 1628, were purchased by our booksellers, and published at London with an English explanation premised, dated 1631. Mr. Babbage (to whose large and rare collection of tables we were much indebted in the original article) has one of these copies; and the English explanation and title is the same as that which was in the same year attached to the asserted reprint of Briggs. We have no doubt that Briggs and Vlacq were served exactly in the same manner. Some copies of Briggs have, after the 'Finis,' another chiliad of logarithms, headed 'Chilias centesima prima,' and arranged like the preceding ones; also, a page of square roots, to eleven decimals, from 101 to 200. In some copies the page of errata follows the additions.

1624. Benjamin Ursinus, 'Magnus Canon Triangulorum Logarithmicus ex voto et consilio Illustr. Neperi p.m. novissimo,' Cologne (at the end, Berlin), 4to. This is an extension of the *original* Naperian logarithms to eight figures, and to every ten seconds: the last places are much more correct. The arrangement is entirely that of Napier, with the addition of the tabular differences, headed *differ.* or D., the heading of the logarithmic tangents being *different.* (contraction of *differentiæ*). There is no preface; but the 'Trigonometria cum magno Logarithmorum canone,' published in the next year at Cologne by Ursinus, contains the necessary explanations. It is bound up with the canon in the copy we have seen; and probably the canon was not issued without it.

(1624.) John Kepler, 'Chilias Logarithmorum,' Marpurg, and (1625) 'Supplementum . . . continens Præcepta de eorum Usu.' These were reprinted by Maseres, in vol. i. of the 'Scriptores Logarithmici.' See a very full account of them also in the first volume of Delambre's History of Modern Astronomy. The logarithms are strictly *Naperian*, 0(1)1000, but four ciphers are put to the end of each number, to make the radius ten millions. There are five columns, of which this is a specimen:—

44° 30′ 26″ | 7010000 | $16^h\ 49^m\ 26^s$ | 3552474 | 42° 4′

The number here is 701, and the sine being 7010000, the angle is 44° 30′ 26″. The logarithm is 3552474. And if 1000 represent 24^h, then 701 represents $16^h\ 49^m\ 26^s$; while if 1000 represent 60°, 701 represents 42° 4′. There are also interscript differences. And thus Kepler originated the species of table now called *logistic*.

1625. Wingate, 'Arithmetique Logarithmique,' Paris (reprinted at Gouda, in 1628, according to Murhard). Wingate was an Englishman who first carried Briggs's logarithms into France. The work was reprinted in England, in the same year. Dodson, Hutton, Ward, &c., say the year of the French publication was 1624; but Lalande and Delambre knew of none previous to 1626, and a copy of the last date which we have examined bears no mark of being a second edition, and refers to nothing as published before, except a tract on the rule of proportion (Gunter's Scale). The logarithms are from Gunter.

But we have found a copy dated 1625, and we are satisfied, from the date of the "privilège" and other things, that this was the first edition. That date is November 4, 1624, and the printing is stated as having been finished April 4, 1625. This edition and that of 1626 are from the same types, except in their title-pages and a page or two of the postfixed explanations. The latter has also a further appendix of differences and some points of explanation. It has also additional (perhaps, for the same thing may have been torn out of our copy of 1625) a folding sheet of mean proportionals between 10 and 1. The contents are,—seven-decimal logarithms of numbers 0(1)1000 with interscript differences; and 0(1′)45° logarithms of sines and tangents, with the complemental parts on opposite pages. These logarithms are from Gunter. This is the introduction of Briggs's logarithms into France; that of Napier's was made, as noted, by B. Vincent.

(1626.) Henrion's 'Logarithms,' Paris. (Dodson, followed by Hutton.) Lalande knew nothing of this work, nor Delambre. All we can learn is from Dechales, who states that Henrion wrote on the proportional compasses in (1623), reprinted in (1681), and on the rule of proportion (which we take to be Gunter's scale) in (1626); and that this last work contains logarithms of numbers up to 2000.

1626. 'Tables des Logarithmes pour les nombres d'un à 10000, composées par Henry Brigge. A. Goude. Par Pierre Rammaseyn.' The negligence of a bookbinder enables us to clear up some confusion, in rather a singular manner. Sherwin states that he examined his table by one of Vlacq's, in large[*] octavo, printed at Gouda in 1626, of which table we find no other mention. The table before us corresponds in every respect, except that there is no author's name; but no one except Vlacq can be mentioned, who was in the least likely to have printed logarithms at *Gouda* in or about 1626. At one time we thought that *this* table was the original of the long series of small tables called after Vlacq; but this was a mistake (see 1625, Gellibrand), and the mistake was partly due to the following circumstances. This table, Gouda, 1626, having the title, when not cut away, above described, and which we have also seen with a Dutch title and preface, is the table which is always bound up at the end of 'Sciographia, or art of Shadowes . . . . by T. W[ells], Esq.,' London, 1635, large octavo. It has a preface by Gellibrand, who was thus accessory to the introduction of *one* small table by Vlacq in the very year in which he (Gellibrand) published *another* small table, the reprints of which were destined to be called by Vlacq's name. That the book was intended to have these logarithms bound at the end is evident from every page of it. Now the fact stands as follows:—A sufficient number of copies of the logarithms having been procured from abroad, the binder was directed to cancel the title-page of the logarithms, and to append them to the work. Accordingly, most copies have no title to the logarithms, which look quite like part of the work. But in some copies the binder has not cancelled as required; we have obtained two (since our first article was written), and there is another in the library of the Royal Society. But in all three copies the title of the logarithms is cut half way up with knife or scissors, as a direction to the binder to cancel it. One of our copies has this Dutch title-page to the table, 'Henrici Briggii Tafel van Logarithmi voor de Ghetallen van een tot 10000. Ter Goude . . . 1626.' And the work (though the same impression as before) has a different title-page and date—namely, 'The Compleat Art of Dyalling . . ., by T. Wells of Deptfort, Esq.,' London, 1637.

---

[*] The work we shall describe would not now be called large octavo; but may have been so in Sherwin's eyes. The octavo sizes (and indeed all the sizes) varied as much as they do in our own day, when between post, demy, royal, &c., we hardly know what is and what is not octavo.

This table contains logarithms of numbers 0 (1) 10,000, to ten decimals, and a complete canon (of logarithms only, and of semiquadrantal form) to every minute and to seven decimals. But the terms cosine, cotangent, cosecant, are not yet introduced.

(162[illegible].) John Maire 'Canon Mesotetologisticus,' &c., Leyden. Such a work is mentioned by Murhard from Scheibel. It contained sines of minutes, to 7 decimals, in Napierian logarithms; with differences to ten seconds.

1627. John Kepler, 'Tabulæ Rudolphinæ,' folio. Among the tables in this celebrated work are the following: First, a variation of the *logistic* table. Next, a table of logarithms, opposite to which are the angles of which they are the *Naperian* logarithms of sines, and adapted to the two ascending arithmetical series 5", 10", ... 60', and 2^m, 4^m, ... 24^h, and to the reciprocal, or harmonic series, 720, 360, 240, ... 1. This table, from its number of terms, he calls a *heptacosias* of *logistic* logarithms: we shall see that Batsch extended the first term; and we note that Kepler here introduced the other. Secondly, a reprint of Napier's own table of sines and (now called) cosines, to two figures less than in Napier. Kepler calls the logarithms of cosines *antilogarithms*, and abandons his right to the word at the same time. For in Napier's semiquadrantal form, the cosines do stand *over against* the sines: but in Kepler's quadrantal form they do not. Napier does not use any distinctive word. Thirdly, Napier's *differentiæ*, called by Kepler *mesologarithms* (being in Napier in the middle), are reprinted separately to every minute of the first ten degrees, for the sake of the latitudes of the planets. Fourthly, more accurate cosines 0 (10") 1° 40', are given.

1628. Adrian Vlacq, 'Arithmetica Logarithmica,' Gouda. The whole hundred chiliads of numbers, from 0 to 100,000, to ten decimals. Sines, &c., to every minute. This work very much displeased* Briggs's friends in England. On the one hand the work is called a *second edition* of Briggs; and, being all in numerals and in Latin, it needed no translation. The pretexts were, first, that copies were scarce in Belgium, which was bad: and that Briggs had omitted the logarithms from 20,000 to 90,000, which was good. On the other hand, it may be held that the supplying of this defect made a new work of the whole; and that the description of it as a second edition of Briggs was too large a concession. A middle course ought to have been taken: Briggs ought to have been consulted. Had this been done, an arrangement would probably have been made which would have satisfied all parties. The error, if any, was purely commercial: there is nothing the least resembling literary plagiarism, but rather the opposite fault, over ascription.

(1630). Bartschius. The tables which Bartschius published independently of his father-in-law (Kepler) had fallen into oblivion, when Eisenschmidt found a copy and republished them with Kepler's *last* tables, and with interscript differences, under the title of 'Joh. Kepleri et Jacobi Bartschii Tabulæ manuales logarithmicæ,' Strasburg, 1700, 12mo. What the titles and dates of the original works were, we can find only from Lipenius, who gives them as follows:—

> Jac. Bartschii 'Tabulæ Novæ Logarithmico-logisticæ,' Leipzig, folio, 1635; and 'Trichil. Hexacosias Logarithmi.' Sagan, 8vo, 1630.

Whether the first was an original edition we do not know: if so, it was posthumous. The reprint by Eisenschmidt contains (from Ursinus, see 1624) a table of logarithmic sines to six figures, 0° (10") 24° (15") 48° (20") 69° (30") 82° (1') 90°; a table of logarithmic tangents 0° (10") 90°, called *mesologarithms;* a more accurate table of logarithmic cosines 0° (2") 2° 7'; an astronomical table which it is not in our plan to describe; and a table called *Trichil-Hexacosias logarithmorum logisticorum*, being a table of what are still called logistic logarithms with 1" and 24^h for first terms.

(1630). J. Faulhaber, 'Ingenieurs-schul., Erster Theyl,' Frankfort. This work contains logarithms, according to Scheibel, who does not give a description.

1631. Norwood, 'Trigonometrie.' Logarithms to seven places; numbers to 10,000, sines, &c. to every minute. We do not know the date of the first edition of Norwood's 'Epitomie': there is one of (1645) (Wilson) and we have one of 1659. The tables are of five decimal places, 0 (1') 45° and 0 (1) 1000; with a separate title 'A Triangular Canon Logarithmical.'

1632. Cavalieri, 'Directorium Generale Uranometricum,' Bologna. Eight-figure logarithms, the ten first thousand numbers in columns of twenty: the sines, &c. to various divisions in different parts of the quadrant. It is very convenient to have a short mode of denoting change of intervals; the following could hardly be misunderstood:—Cavalieri's tables are, 0 (1") 5 (5") 10' (10") 20' (20") 30' (30") 1° 30' (1') 45°. The table of logarithmic versed sines is said to be the first given. Cavalieri gave logarithms again in his trigonometry (see 1643); and also in his 'Tabula Trigonometrica,' of which we do not know the date.

1633. Gellibrand, 'Trigonometria Britannica,' Gouda. Briggs's work, which he did not live quite to complete. Sines, tangents, and secants, with logarithms of the sines and tangents: sines to fifteen decimals, tangents and secants to ten, logarithms of sines to fourteen decimals, logarithms of tangents to ten decimals. It is to hundredths of degrees, not to minutes.

1633. Vlacq, 'Trigonometrica Artificialis,' Gouda. Logarithms of sines, tangents, and secants, to every ten seconds, and to ten places of decimals. Twenty thousand of Briggs's logarithms of numbers are added.

1633. Nathaniel Roe, 'Tabulæ Logarithmicæ,' London. Seven-figure numbers to 100 thousand, ten-figure sines, &c. to hundredths of degrees. The first table in which attempt at compression was made: the numbers are in columns of fifties, the first figures of the logarithms being at the top. A good model for a small and clear type. The explanations are called Wingate's, whose name is by the announcement made so conspicuous in the title-page, that the whole book must have often been attributed to him.

1633. J. B. Morin, 'Trigonometriæ Canonicæ Libri Tres,' Paris. Seven-decimal Logarithms; of Numbers 0 (1) 1000, with interscript differences; of Sines and Tangents 0 (1') 45°. The decimal point is not used.

(1634). Cruger. Kästner gives Dantzig as the place. The logarithms are Naperian, according to him.

1634. Herigone, 'Cursus Mathematicus,' vol. iii., Paris. Said to be the first digested course of mathematics; contains logarithms, apparently from Wingate's French of 1626.

(1634). Frobenius, 'Clavis Univ. Trigon.' The (by that time) usual Briggs's logarithms to seven places.

(1634). Cruger, 'Praxis Trig. Logarith. cum Logar. Tab.', &c., Amsterdam.

(1635). Cruger, 'Doctrina Astronomiæ,' Dantzig. Contains logarithmic tables.

1635. Anonymous, 'Logarithmeticall Table,' London. [Attributed to Wingate. Dodson is followed by Hutton in saying that Wingate published an English edition of his French logarithms. But Hutton never saw any prior to this of 1635, and we can find no mention of anything of Wingate's translated from French, except (in an old catalogue which gives no dates) 'The Construction and Use of the Logarithmeticall Tables,' not tables themselves. The logarithms of the table now before us are of six figures, and for the first time units' figures are at the head of the columns, and the tens down the margin. There are tables of 1632, attributed to Wingate.]

We allow the preceding paragraph in [ ] to stand as in the 'Penny Cyclopædia,' in illustration of the difference between the utmost that can be got from second-hand sources, and the results of a look at the original. We have found a copy of the following work:—'*Λογαριθμοτεχνία*, or the Construction and Use of the Logarithmeticall Tables, ... first published in the French Tongue by Edmund Wingate... and, after translated into English by the same author. The third Edition, diligently corrected and enlarged by the Author himself,' London, 1648, 12mo. The work is the letter-press of Wingate of 1625 and 1626, already noticed, translated into English. The tables have a French title of 1635, 'Une table logarithmique... Imprimé à Londres.' But our separate copy of the tables, being that which heads this article, has an English title, though both tables are from one type. No doubt the first edition was of 1635, and the supply of tables lasted several editions of the supply of text. Wingate was a wealthy man, and probably found his disposition to alter and amend his descriptions outrun the sale of the work. But the tables are not reprints of the French tables of 1625. They are to six figures, not seven; the numbers are 0 (1) 10,000 ranged by double entry, three digits and one: and the trigonometrical tables are arranged in a manner more like that now in use.

1635. Henry Gellibrand, 'An Institution Trigonometricall,' London. Seven decimals; logarithms of numbers 0 (1) 10,000; sines, tangents, and secants, with logarithms of sines and tangents, dividing the page into two parts, one of three columns, the other of two. The form not semiquadrantal, but quadrantal, with the complemental degree (inverted) on the opposite page. No differences; some subsidiary tables for astronomy and navigation; the name of Briggs prefixed to the logarithms of numbers only. This is the form of a series of tables which ran through many continental editions; but they all bear the name of Vlacq. It is stated that Vlacq's first edition of them appeared in (1636): and Dechales (i. 22) describes a work of Vlacq of precisely the above contents, as of Gouda (1636). Early editions of small works are often lost to history. Now we have seen that Vlacq was a rapid appropriator of English ideas: in less than four years he reproduced Briggs, with the 70,000 missing logarithms, and a table of sines, &c. We must suppose that he seized upon Gellibrand's form, and immediately reprinted it. We have seen (1626) that Vlacq's previous idea of a small table had been very different.

The originator, then, of the long succession of small tables is Gellibrand. All the tables of this *Gellibrand model* are known at a glance by containing, on one page, sines, tangents, secants, with logarithms of sines and tangents, and some *white* between the sines, &c., and the logarithms. Under the name of Vlacq, his idea prevailed till 1760, when Lalande first commenced a new series. Lalande himself originated a third series in 1805; and the next series begins, for England, with the reprint of Lalande by the Useful Knowledge Society in 1839. Schulze speaks of some small tables by Wolf, as being as common in Germany as those of Vlacq: of these we do not remember to have met with a copy.

---

* Norwood, in his Trigonometry (preface dated November 1, 1631), reminds his readers that when he quotes the 'Arithmetica Logarithmica' he means Briggs's book of 1624, not that put forth a month since in English (see *ante*, 1624, Briggs), "being nothing like his, nor worthy his name." He blames Vlacq for his "second edition" of Briggs's work, against Briggs's "mind and liking," which he says frustrated the second edition of the original, besides omitting some things of special moment.

1643. F. B. Cavalieri, 'Trigonometria plana et sphærica,' Bologna. Seven-decimal Briggs's logarithms 0 (1) 1000, with interscript differences; also sines, tangents, secants, and their logarithms, 0 (10″) 30′ (30″) 1° (1′) 45°. But the decimal point is not used. The logarithms of sine, tangent, secant, are styled logarithm, mesologarithm, tomologarithm.

1651. Vincent Wing, 'Harmonicon Coeleste,' London. The logarithms have separate title-pages, and might, if torn out, pass for separate works. They have the decimal point and are to six decimal places. Sines and tangents 0 (1′) 45°; numbers, in decads, 0 (1) 1010, without characteristics. Wing was a much more learned man than his reputation (which is that of an almanac-maker) would imply.

1654. John Newton, 'Institutio Mathematica,' London, 2 vols. 12mo. Contains tables.

1657. Oughtred's 'Trigonometrie,' London, published both in English and Latin in the same year. The logarithms however are from the same type, with the Latin title in both: they are complete six-figure logarithms; the numbers, which go to 10,000, having seven figures. The trigonometrical part contains sines, tangents, and secants, with the logarithms of sines and tangents. The table is quadrantal, the supplemental degree being in the opposite page inverted. It divides the degree into 100 parts, though each part is called a *minute*.

(1657). John Newton, 'Help to Calculation,' &c., for converting sexagenary tables into decimal by logarithms.

1658. John Newton, 'Trigonometria Britannica,' London. The logarithms of sines, &c., are 0 (0°·001) 3° (0°·01) 45°, to 8 decimals; also sines to 15 and logarithms of sines to 14 decimals, 45° (15′) 90°. The logarithms of numbers are thrown into the form which they have ever since preserved in seven-figure tables. But, instead of differences to the logarithms of numbers, five-decimal logarithms of differences are given.

1668. John Newton, 'The Scale of Interest, or the use of Decimal Fractions.' Here is a table of logarithms to six decimals 0 (1) 10000 arranged in lines of decads, with a separate table of proportional parts. This is the first attempt at a school-book and a workman's book. There is an appendix of application to carpentry and gauging.

1669. Phillippes, 'A Mathematical Manual.' Six-figure logarithms, common and trigonometrical without secants or cosecants, 0 (1) 10000, 0 (1′) 45°.

1679. 'A table containing ten Miliads....' and 'A triangular Canon Logarithmical,' London. Seven-decimal tables, numbers 0 (1) 10,000, and sines, tangents, and secants 0 (1′) 45°. These tables belong to some work, from which our copy is cut out: signatures from Aaa to Ttt, quarto.

1681. Vlacq, 'Tabulæ Sinuum, &c., Amsterdam: also 1683. Vlacq, 'Tables de Sinus,' &c., Amsterdam; and 1689, Vlacq, 'Tabellen der Sinuum, &c.,' Amsterdam. These have the same introduction, one in Latin, the other in French, the third in German, have sines, tangents, secants, and logarithms of sines and tangents, to every minute and to seven decimals. Also, seven-decimal logarithms from 1 to 10,000, headed 'H. Briggii Tabula Logarithmorum.' The first and second are different prints; and that of 1683, which passes for the most correct (see 1697, Ozanam), is in a beautifully legible bold type, large for so small a book. There are those who would be glad to use it now. See above, at the year 1635, Gellibrand.

1681. Jonas Moore, 'New Systeme of the Mathematicks,' London, 2 vols. 4to. In the second volume, as part of an extensive system of tables for navigation, are found tables of logarithms of numbers to seven decimals 0 (1) 10,000, with tables of proportional parts 44 (1) 4320; sines, tangents, and secants, and their logarithms 0 (1′) 45°. Also, for the first time in England, a complete minute-table of natural and logarithmic versed sines.

1685. Ozanam, 'Tables des Sinus,' &c., Paris. This is really Vlacq in every particular as to the tables, though his name is not mentioned. The tables are attached to a work on trigonometry. Many a writer thought that the body of this work consisted in his own trigonometry, or surveying, &c., and that the table was an accessory of which no notice need be taken. And so, in our own day, many persons who are quite above plagarism of text think it no sin to borrow plates or diagrams without acknowledgment.

1690. Dechales, 'Cursus seu Mundus Mathematicus.' The first volume has seven-decimal tables; logarithms of numbers 0 (1) 10000; of sines and tangents 0 (1′) 45°, and the sines and tangents also.

1690. Wm. Leybourn, 'Cursus Mathematicus.' This book has internal evidence of having been written before 1660. Seven-decimal logarithms of numbers 0 (1) 10000; six-figure logistic logarithms 0 (1″) 1° and 1° (1′) 1° 12′; *signs*, tangents, and secants, &c., 0 (1′) 45°; the names cosine and secant not used.

1697. Ozanam, 'Tables des Sinus,' &c., Paris. This is a reprint (see 1685) without trigonometry, and Vlacq is acknowledged. The printing is from the edition of the Hague, 1665, which ranks amongst the most correct; the correction from that of Amsterdam, 1683, which passes for the more correct. Two years afterwards, in 1699, the tables only were reprinted (Paris), the name of Vlacq was restored to the title-page, and the 'Au Lecteur,' written by Ozanam in 1697, was added at the end.

1699. John Wing (nephew of Vincent), 'A compleat Body of Surveying, formerly publish'd by Vincent Wing,' London. Five-decimal logarithms of sines and tangents, 0 (10′) 45°; of numbers, 0 (1) 1000.

(1704). J. H[arris], 'Table of Logarithms,' quarto, mentioned in Hutton's sale catalogue.

1705. (Second edition.) Anonymous, 'A Table of Logarithms for Numbers increasing in their natural order, &c.,' London. Six-decimal logarithms of numbers 0 (1) 10000. The trigonometrical part has a separate title, 1704, 'A Triangular Canon Logarithmical,' London. Six-decimal logarithms of sines, tangents, and secants 0 (1′) 45°. So far as appears, this table was got up by J. Seller and C. Price, mathematical-instrument makers, who seem to have desired to sell their own table of logarithms as well as their own quadrants. This table appears to be a second edition, so called, of a table precisely resembling it, except only in having seven decimals, attached to the 'Practical Navigation' of the same John Seller, who appears as the *author*.

(1706). Sherwin, 'Mathematical Tables,' London. The first work, we believe, in which the proportional parts are in the same page with the logarithms; and the common differences in the trigonometrical logarithms made *common*. Second edition, 1717; third, revised by Gardiner, and the best, 1742; fifth and last, 1771, very erroneous—the most inaccurate table Hutton ever met with.

1710. John Harris, 'Lexicon Technicum,' vol. ii. This volume contains seven-decimal tables of logarithms 0(1)10,000, and a complete canon (including versed sines), 0(1′)45°, both natural and logarithmic. There is also a table of proportional parts for every integer from 44 to 4320. These tables, except the last, seem to be taken from Sherwin.

1717. Abraham Sharp, 'Geometry Improved,' London. A large table of areas of the segments of circles: but it contains logarithms of all numbers to 100, and all primes under 1100, true to sixty decimals; 63 decimals of logarithms 999990(1)1000000 with differences to the tenth; and 63 decimals of the logarithms 1000001(1)1000010. Also an immense mass of results on the regular solids.

(1721). 'Magnus Canon Logarithmorum .... Typis Sinensibus in Aula Pekinensi jussu Imperatoris excusus.' In this year was printed at Pekin, by command of the emperor Kang-Hi, in Chinese type and in three folio volumes, Vlacq's logarithmic tables of sines, &c., to ten seconds, and of numbers to 100,000. (Vega, who had seen a copy at Vienna.) The Royal Society possesses some Chinese logarithms, and, as usual, there were in 1827 some who believed that the Chinese had possessed logarithms from all eternity. Mr. Babbage ('Astron. Soc. Notices,' vol. i. p. 9), examined these tables, and found that six slight errors which run through most European tables were committed in them. Only Vega and the last impressions of Callet were free from these errors. It appears that the Chinese, according to their usual practice, had taken from the European work republished at Pekin, without any allusion to the source.

1741. Deparcieux, 'Nouveaux Traités de Trigonométrie Rectiligne et Sphérique,' Paris. Deparcieux is so much better known by his tables of annuities, that his other writings * are neglected. The tables are all to seven decimals (though the decimal point is not used). There are logarithms of numbers 0 (1) 20000; sines, tangents, and secants, &c., 0 (10′) 5 (1′) 45°, and logarithms of sines and tangents. This is the earliest table we remember to have seen in which the argument of degrees, minutes, and seconds accompanies the logarithms of numbers. The book is also distinguished by its gnomonical tables, and by the excellence of its solid diagrams.

1742. Dodson, 'Antilogarithmic Canon,' London. This work was unique of its kind until 1849: it contains the number, to eleven figures, corresponding to every logarithm from ·00001 to 1·00000: the author † corrected the faults in most copies with his own hand. Harriot began such a table, according to Wallis, and Dr. Pell told Wallis that Warner had finished the table, and that it was in the hands of Dr. Busby, master of Westminster School. It was never published, and is probably lost. All our efforts to trace it, by help of published letters, &c., lead to the conclusion that, if existing, it must be among Lord Macclesfield's unexamined manuscripts at Shireburn Castle: this is by no means improbable.

---

* When a person is distinguished by one particular work, his other, and particularly his previous, writings, even on the same subject, go out of notice. How many persons, for instance, know that Laplace published (separately from the Memoirs of the Academy) a small work on the elliptic motion and on the figures of the planets in 1784? (See Lalande, Bibl. Astron. ann. 1784.) And how many biographical accounts of Laplace mention it?

† In the Phil. Mag. for 1853 are extracts from the diary of Reuben Burrow, who states that Robertson (the author of the Navigation) told him that William Jones (better known than his son among the mathematicians) wrote Dodson's preface, because Dodson wrote such a confused style that it had neither head nor tail. This was not the case, as any one may see: unless indeed Dodson got a friend to write all he published. But there is also something like a charge of plagiarism on a different matter; and there are imputations against other persons. We do not object to the production of old diaries; but when they contain imputations, it is of importance that their authors should be truly painted. Burrow's biography, extracts from which accompany those from the diary, does no more than allude to "*eccentricities in private life which frequently attend genius*," and "habits formed by casualty and the necessities of the moment, rather than by design and the prudent hand of a master." The truth is that Burrow, a very able mathematician, was envious and foul-mouthed to an extent which it would be an insult to thousands of self-elevated men to palliate by the plea of want of early education. Of this we shall give an instance. Green and Wales, two very worthy as well as able men, were successively the astronomers who accompanied Captain Cook in his voyages: probably Burrow had been a competitor for the post. In his copy of any book published by either of them, Burrow usually wrote some scurrilous aspersion, of which we have seen several

1742. Gardiner, 'Tables of Logarithms,' London. Numbers 1—100100, sines, &c., 0 (1″) 72′ (10″) 45°, all to seven places, with logistic logarithms, and logarithms 0 (1) 1143 and 101000 (1) 101139, and numbers to logarithms ·00001 (·00001) ·00139, to twenty decimal places. Rare, and much esteemed for accuracy: the author[*] corrected the faults with his own hand. Few copies were printed.

1742. Anonymous, printed by J. F. Gleditschen, 'Des vollständigen Mathematischen Lexici zweyter Theil,' Leipzig. Here we have squares and cubes 0 (1) 10,000; seven-decimal logarithms of sines, tangents, and secants 0 (1′) 45°; logarithms of numbers 0 (1) 20000; sines, tangents, and secants 0 (1′) 45° to seven decimals; factors of odd numbers not ending with 5, to 10,000.

1743. Rivard, 'Tables des Sinus, &c.,' Paris, with the official "approbation" of Clairaut. Seven-decimal logarithms of sines, tangents, and secants 0 (1′) 45°; sines and tangents to five decimals; secants in a separate table; logarithms of numbers 0 (1) 20000: all with characteristics and no decimal points.

1747. James Dodson, 'The Calculator .... adapted to Science, Business, and Pleasure,' London. A large collection of small tables, with sufficient, though not the most convenient, seven-figure logarithms. If a person of varied mathematical pursuits wanted a book, say for travelling, he would not easily find one which would answer more purposes at a pinch than the one we now speak of. The contents are too varied for enumeration.

1757. In the original articles there was a gap from 1742 to 1770, which shows that there was a lull in the publication of pure mathematical tables. The period was one in which the mathematicians were very much absorbed in physical investigation. When this is the case, tables of pure mathematics find their way into works of physics and astronomy under headings of application. Should any one ever enlarge upon our plan, he must search astronomical and other works for such tables as the following: Thomas Barker, 'Account of comets .... with new tables,' London, 4to., 1757. The tables give, for focal distance unity, and for angles of anomaly 0 (5′) 180°, the distance of a point from the focus of a parabola, and the area of the sector on the supposition that at 90° the sector is 100°. Halley had given a table of the same kind on a much smaller scale: and Euler, in the 'Theoria Motuum Planetarum,' in 1744, had given the area of the parabola for each degree of anomaly. Professor Schumacher (September 3, 1846), wrote to us as follows: "Professor Knorre has sent me this (Barker's) table, calculated from 0° to 180° of anomaly, from 10″ to 10″ (like Callet's sines), to see if I can get it printed. It is a work of immense labour, executed by Mr. Rupertus in Russia. The booksellers, of course, will not undertake it." We have heard nothing more of this table. More tables than we think it desirable to describe here, on the ellipse, parabola, and hyperbola, as orbits of a comet, are given in 'Methods of computing the Orbit of a Comet or Planet,' being the appendix to the third volume of Bowditch's translation of the 'Mécanique Céleste,' Boston (U.S.), 1834, 4to.

(1760). Lacaille and Lalande first published a small table: Marie reprinted it in 1768: there were editions in (1781, 1791, 1799). So far Lalande, in his preface of 1805 (see that year): none of these works have come to our hands.

1770. J. H. Lambert, 'Zusätze zu den Logarithmischen und Trigonometrischen Tabellen.' This is a miscellaneous collection of tables and formulæ, containing—Primes, at least divisors of all odd numbers which do not divide by 3 or 5, up to 102,000; three-digit terminations of odd squares: first ten multiples of all prime numbers up to 313; primes alone up to 102,000; powers of 2 as far as the 70th, and of 3 and 5 as far as the 50th; hyperbolic logarithms, seven decimals, 0 (1) 100, and 1 (·01) 10, and 1 (1) 10 to 25 places; numbers which divide by 2, 3, 5, or 7 only, or their powers or products (except those which divide by 2 or 3 only), up to 10,000; sines of 3° and its multiples expressed quadratically; cyclometrical ratio; 27 decimal arcs 0 (1°) 100° (20°) 120° (30°) 360°, and for minutes and seconds; five-decimal sines and nine multiples 0 (1°) 90°; seven-decimal sines, tangents, and secants, and logarithms of sines and tangents 0 (1°) 90°; tables for facilitating cubic equations; sines and cosines of *hyperbolic trigonometry*, the only table of the kind we have met with; squares and cubes 0 (1) 1000; figurate numbers to the 12th order, 30 of each; eight-decimal powers of fractions 0 (·01) 1 to the 11th power; seven-decimal square roots 0 (1) 100; with smaller matters and many algebraical formulæ of development. There is said to be another edition of this useful miscellany, Lisbon (1798).

1770. Reprint of Gardiner at Avignon, by Pezenas, Dumas, and Blanchard, with the first four degrees to single seconds, from a manuscript which Mouton had bequeathed to the Academy of Sciences. The three industrious editors, all of them priests, who found time to complete this useful undertaking, modestly withheld their names; but Lalande, who was in communication with them, and who was an old pupil of Dumas, has recorded them. There was a reprint of some sort at Florence, in (1782), and we have been informed of a third Italian edition, so-called, Florence (1810), badly printed, and containing also logarithms of prime numbers up to 6607, to twenty figures.

(1772). Gherli's 'Logarithms,' Modena. Very much the same as Hutton's in their contents.

1775. Douwes 'Tafellen behelzende de Sinussen .... als mede de Logarithmen,' &c., Amsterdam. A complete minute-canon to seven decimal places; followed by logarithms to seven places; versed sines and logarithms on the same scale to 90 degrees; logarithms of numbers from 1 to 101000; and traverse tables.

1778. J. C. Schulze, 'Neue und erweiterte Sammlung logarithmischer . . . Tafeln,' Berlin. Also, 'Recueil de tables logarithmiques . . . .' The titles and preliminary explanations are both in French and German. Two volumes. This is a valuable and original collection. It contains the usual seven-figure tables 0 (1) 101000; a page of multiples of ·434 . . . and its reciprocal to 48 places, and powers of 2·718 . . . to 28 figures; *Wolfram's*[*] hyperbolic logarithms of all numbers from 1 to 2200, and from thence to 10,000 for all numbers not divisible by any single digit, all to *forty-eight decimal places;* common logarithms to seven decimals of sines and tangents 0 (1″) 2°; logistic logarithms to four decimals 0 (1″) 1°; a complete canon 0 (10″) 4° (1′) 45° containing sines, tangents, and secants to seven decimals, common logarithms of sines and tangents to seven decimals, *Naperian* (not hyperbolic) logarithms of sines and tangents to eight decimals; first nine multiples of sines of every degree to five decimals; lengths of arcs 0 (1°) 360° to twenty-seven decimals; ditto 0 (1′) 1° and 0 (1″) 1′; powers of fractions 0 (·01) 1 as far as the eleventh, to eight decimals; squares and cubes 0 (1) 1000; square and cube roots 0 (1) 1000 to seven decimals; binomial coefficients 0 (·01) 1 to six factors; a table for the fall of bodies, of rational right-angled triangles with the angles, and small tables of specific gravities and of weights and measures. Half-a-dozen of Wolfram's logarithms which were accidentally missing in consequence of an illness, are supplied in the Berlin Ephemeris for 1783, p. 191. The *Naperian* logarithms of sines and tangents are an abbreviation of Ursinus, (see 1624).

(1783). Vega 'Logarithmische Trigonometrische und andere . . Tafeln und Formeln,' Vienna. This was Vega's first work, and we have never met with it. (Octavo.)

1783. Callet, 'Tables Portatives de Logarithmes, publiées à Londres par Gardiner,' &c., Paris. The first edition of Callet, as it is called, was really made from Gardiner's tables "augmentées et perfectionnées dans leur disposition par M. Callet." Callet added as much of each kind of table as would leave no white in his last page, and, from Mouton, completed the single-second table of sines and tangents up to 2°. Here also first occurs the broken line at the change of the third figure. On this edition Hutton, commonly said to have much prejudice against French men and things, says "it is but justice to remark the extraordinary spirit and elegance with which the learned men and the artisans of the French nation undertake and execute works of merit:" and the compliment is well deserved by the beauty of the type and the general accuracy of the work. The contents are seven figure logarithms of members 0 (1) 102960, of sines 0 (1″) 2°, of sines and tangents 0 (10″) 45°; logistic logarithms; logarithms to twenty decimals 0 (1) 1000 and for primes up to 1161; also for 101000 (1) 101179 with three orders of differences; 20 figures of numbers to logarithms ·00001 (·00001) ·00179 with the same differences; hyperbolic logarithms to seven decimals 1 (·01) 10·59.

1795 (new tirage, 1821, with many errors corrected). Callet,

---

instances. But in the 'Misc. Scient. Cur.,' of which Green and Wales were co-editors, he felt that the conjunction of his luminaries demanded a spring-tide, and he accordingly wrote the following eccentricity of genius in private life on the fly-leaf of his copy, now before us, and left it to posterity:—"Miscellanea Scientifica Curiosia, or a Balderdash Miscellany of damn'd Stupid, Raggamuffin, Methodistical Nonsense and Spuability. By two of the most stupid and most dirty of all possible Fools, Rogues, and Scoundrels; viz^{t}., John Green, A.M., late Tub-thumper, now Soul-driver in Hell; and William Wales, — brusher at Christ's Hospital, not only the dirtiest Scoundrel that God ever made, but the dirtiest rascal that he possibly could make. Amen." There are other notes in the book about these persons and others as well; but this is enough. The reader will excuse the production of such coarseness, in consideration of the expediency of fixing the value of extracts made, or to be made, from Burrow's diary.

[*] The work had a small list of very influential subscribers. Of about 120 names of persons and institutions in the list, one in three is the name of a person now known by name to any smatterer in scientific and literary history. Few subscription lists would give such a result after a century of existence. The work thus recommended makes an epoch in the history of tables.

[*] This table was the work of Lieut. Wolfram, of the Dutch artillery, and took six years of hard labour. It is one of the most striking additions to the *fundamenta* of the subject which has been made in modern times. Delambre ('Hist. Astr. Mod.,' v. i., p. 501, &c.) introduces his comparisons of Napier and Wolfram so abruptly, and so many pages elapse before the reader can find out who the latter was, that most probably many have inferred that the two were contemporaries. But this is Delambre's way, and is often liable to confuse a reader who has no warning on the subject. With a work before him from which he is drawing his materials, he perhaps never mentions it till the end of his remarks, or perhaps casually in the middle, though until such mention is made, all he says is very liable to be misunderstood.

'Tables Portatives,' &c., Paris. Two volumes. This second edition, *stereotyped* by Firmin Didot, is one of the most correct and convenient as well as extensive works in existence: many persons prefer it to any other. It contains the usual seven-figure logarithms from 1 to 108000—common and hyperbolic logarithms, each to 20 decimals, up to 1200—logarithms, common and hyperbolic, to 18 decimals, with first, second, and third differences, from 101000 to 101179—numbers to logarithms, common and hyperbolic (to 20 figures), from ·00001 to 00179, with the same differences; common logarithms[*] to 61 decimals, and hyperbolic to 48, to all numbers from 1 to 100 and all primes to 1097; the same for numbers from 999980 to 1000021—multiples of 2·30258 . . . and ·43429 . . . . to 100 times—arcs to 25 decimals, for both sexagesimal and centesimal division—seven-figure logarithmic sines, &c. for each minute of the centesimal division—sines (15 decimals) and their logarithms (the remaining places up to 14, the first seven being in the last table) for centesimal degrees and tenths—proportional parts—sexagesimal seven-figure logarithms of sines and tangents 0 (1″) 5° (10″) 45°—logistic logarithms. Those tables are tolerably, but, we believe, not extremely, correct in all parts, except in the latest tirage. The tirage of 1827, on yellow paper, was taken to accompany Mr. Babbage's logarithms.

1784. M. Robert, curate of St. Geneviève à Toul, sent Lalande ('Ency. Meth.' Tables.) a manuscript volume containing sines to every second, to how many places he does not say; shortly afterwards he sent the tangents. Lalande gives a hint that the approaching publication of Taylor's logarithms prevented any steps being taken to print these. He also states that there was in the library of the Academy of Sciences a manuscript of Mouton, giving the logarithmic sines and tangents of 0 (1″) 4° to eleven figures; we suppose he means to ten places of decimals (see 1770). M. Robert's manuscript came into Delambre's possession, and was bought at the sale of his books by Mr. Babbage, in whose possession it now is. It is in two large folio volumes, the figures (to seven decimals) being written in printed skeleton columns. Some corrections of Callet, discovered by means of this manuscript, were printed in one of the nautical almanacs.

1785. Hutton, 'Mathematical Tables,' London. Many editions, the second in 1794; one in 1849. A very correct set, with sines, tangents, &c., and versed sines, complete, both natural and logarithmic. For those who want seven places, and can have but one book, there is none better. The additional matters, especially the historical introduction, are well-known.

1789. William Garrard 'Copious Trigonometrical Tables.' This is one of the largest of what are called in navigation *traverse tables*. For every integer hypothenuse from 1 to 300 are given, to two decimals, the value of the base and altitude, for every angle 0 (10′) 90°.

1792. Michael Taylor, 'Tables of Logarithms,' London. In the trigonometrical part the sines and tangents are *to every second*. The errata of this work have been published in various nautical almanacs. This widely used work, the first to which 0′ (1″) 90° applies, was by a most industrious computer, attached to the staff of the 'Nautical Almanac.' He died just before the last half sheet was printed; and Dr. Maskelyne supplied the introductory matter. This book, like others published by the Admiralty, was not sufficiently advertised. It sold as a second-hand book, neither sellers nor buyers knowing that Mr. Murray had plenty on hand. For ought we know, the same thing may still go on.

1791-1807. Maseres, 'Scriptores Logarithmici,' London. The first volume contains a reprint of Kepler's Logarithms, the sixth and last of Napier's work of 1614, and John Sperdell's logarithms of numbers.

1794 or 1795. (an III., a Port-Malo, chez L. H. Hovius, fils) Tables des logarithmes des nombres, depuis 1 jus qu'à 10700 . . . . dresseés á l'usage de la navigation . . . . Six figure logarithms of the common type, in all respects but one, and that one curious and perhaps unique. A rectangle which *corners* with the upper right of the page, has an extent of 30′ with the usual semi-quadrantal arrangement of trigonometrical logarithms. In the remaining gnomon comes a part of the table of logarithms of numbers. At ninety of these to a page, the logarithms of numbers come so near in the book to the corresponding figures in the sines and tangents, up to 45°, that a person who wants the natural sine or tangent has very little turning of pages to do. But this is no help to the second half of the sines, or the first half of the cosines. When the half-quadrant is finished, the remaining logarithms of numbers ran on in the usual way. Had the author made a full quadrantal arrangement, and checked the speed of his logarithms of numbers a little, by additional lead or otherwise, as he went on, he might have made something which would possibly have been judged worthy of imitation, in tables specially intended for astronomers and other trigonometers.

1795. The Abbé Borne, a Frenchman, gave a table of logarithms of numbers of a peculiar kind at the end of his 'Principie ragionati de Aritmetica,' Pesaro, 8vo. All numbers which end with 1, 3, 7, 9, are found by double entry; thus 6973 is in column headed 69, and row fronted 73. If this were a prime number, seven decimals of logarithm would have been entered: as it is, the lowest divisor, 19, is entered. Thus, in 20 pages there is a *potential* table 0 (1) 10,000. But the Abbé did not see that the same space would have contained the logarithms of all odd numbers not ending with 5: and these, with the logarithms of 2 and 5 printed at the head of every page, would have done better service than the factors. Authors often forget that they do not save either space or cost of printing by what appear abbreviations or omissions in the manuscript: the saving is but so much of what the printer calls *white*, which is done by types; and white is black, both in the room it takes and in the printer's bill.

1794. George Vega, 'Thesaurus Logarithmorum completus,' Leipzig, folio. Vega's edition of Vlacq. See Vlacq of 1628 and 1633. A very correct work: a ducat was offered for every error detected. There is also a German title-page, and the explanations are both in German and Latin. This is, no doubt, up to this time, *the* table of logarithms; the one of all others to which ultimate reference should be made in questions of accuracy. Its contents are,—a *ten*-decimal table of common logarithms 1 (1) 101000 distributed in the common manner, a decad in each line of the double page, with the differences arranged in the same way, and tables of proportional parts for the first three figures of the differences. Logarithmic sines and tangents to 10 decimals, 0 (1″) 2° (10″) 45°. Sines 0 (1″) 12′ to ten decimals. Lengths of arcs to 11 decimals. Wolfram's *hyperbolic* logarithms (see 1778) above described, reprinted from Schulze.

1794. J. J. Girtanner, 'Logarithmische Tafeln zur Abkurzung kaufmannischer Rechnungen,' commercial logarithms. The plan is to have logarithmic tables for integers and different sorts of fractions, among which eighths, tenths, sixteenths, and sixtieths are conspicuous. But it will not do: Mohammed must go to the mountain. When coinage, weights, and measures, are decimalised, the use of logarithms will follow as a matter of course. It is useless trying to bring logarithms to ordinary fractions.

1797 (2 vols. 2nd ed., or rather second work) and 1812. Vega, 'Tabulæ Logarithmico-Trigonometricæ,' Leipsic. Titles and introduction both in German and Latin. The usual logarithms of numbers, 0 (1) 101000; logarithms of sines 0 (0″·1) 1′, and 0 (1″) 1° 30′, and the full canon 0 (10″) 6° 3′ (1′) 45°—divisors and primes already noticed—eight-figure hyperbolic logarithms from 1 to 1000, and for all primes up to 10,000—powers of 2·71828, and their common logarithms (from exponent ·01 to 10·00). First ten powers of numbers up to 50; squares and cubes of numbers up to those of 1000, &c.,—logistic logarithms, binomial co-efficients, and astronomical tables various. There are various smaller editions from Vega, as at Leipsic (1820), and (1826).

1799. J. P. Hobert and L. Ideler, 'Nouvelles Tables Trigonométriques calculées pour la Division décimale du Quart de Cercle,' Berlin. Delambre speaks highly of this table; but he is wrong in saying it subdivides the quadrant as minutely as those which himself and Borda published. Meaning by 1° the hundredth of the right angle, and 1′ being 0°·01, and so on, Hobert and Ideler's division of the quadrant is 0 (10″) 3° (1′) 50°; but Delambre and Borda's are as below. The Berlin table gives sines and tangents and their logarithms, through the quadrant; the Paris table gives logarithms only. The former has no logarithms of numbers except 0 (1) 1100 and 999980 (1) 1000021, all to 36 decimals.

1800 or 1801. (An. IX.) Delambre and Borda, 'Tables Trigonométriques Décimales,' Paris. These tables were corrected from the grand 'Tables du Cadastre,' still unpublished.[*] [PRONY, in BIOG. DIV.] They contain, the common logarithms of numbers to seven decimals, 11-decimal logarithms of numbers from 1 to 1000, and from 100,000 to 102,000°; 11-decimal logarithmic sines, cosines, tangents, and cotangents 0 (10″ centesimal) 10′ and 0 (10′) 100; 11-figure hyperbolic logarithms from 1 to 1000; 7-decimal logarithms of sines and tangents 0 (1″) 3° (10″) 40° (1′) 50° centesimal.

1802. J. R. Teschemacher. 'Tables calculated for the Arbitration of Exchanges, both Simple and Compound,' London. This is a book of commercial *logarithms*, though the author wisely avoided frightening the merchant by mentioning the word in any part of his book. There is one table of logarithms for the exchange between London and each other place: the tables average about a page each. With this limited range, the logarithms are really effectively applied to commercial purposes, and operations are very much simplified. There is no need of a separate book of logarithms: all that the reader knows or needs to know is that certain nameless figures are to be used in a certain easy way. We are fully of opinion that such a work might be very useful.

1804. De la Caille, De la Lande and Marie, 'Tables de Logarithmes,' Paris. Six decimal places, which probably the preceding ones had, (see 1760). The trigonometrical tables 0 (1′) 45° as usual, with differences for 1″: the numbers 0 (1) 21600. La Lande has forgotten to mention this edition; or perhaps it was not published when he was preparing the work next mentioned.

1805. De la Lande, 'Tables de Logarithmes,' Paris. *Stereotyped.* See 1760, 1831.

1806. Thomas Whiting. 'Portable Mathematical Tables,' London. Six-figure logarithms. This book is a striking proof that in the old figure, the reduction of the thickness of the type very much increases the legibility. This is a very easy book to read, and would exactly suit those who want a large type in a small book.

[*] The last 51 places are given, the first ten being accessible in a former table.

[*] There was once a commencement of the printing, and we have seen some of the proofs.

1808. Ebert. 'Adriani Vlacq Tabulæ Sinuum,' &c. Leipzig. The contents are as before described (1635). This is a new (and apparently the last) edition of Ebert's, whose preface is dated 1790. Besides the contents above described there are logarithmic sines and tangents for each second of the first degree, and squares and cubes of all integers up to 1000.

1809. George Douglas. 'Mathematical Tables,' Edinburgh. A long preface; followed by seven-decimal logarithms from 1 to 10,000, ten in a line, in the usual way. Two supplemental tables, with the same from 10,000 to 11,000, and from 100,000 to 101,000. A complete logarithmic canon for minutes, to seven decimals. A corresponding canon of natural sines, &c. Natural and logarithmic versed sines, the former to 90°, the latter continued to 180°. A table to convert sexagesimals into decimals; and logarithms from 1 to 180, to 15 decimals. A different arrangement from the usual one in several respects. No differences in any part of the tables.

(1812). In Zach's 'Monathliche Correspondenz,' vol. xxvi., page 498, Gauss proposed his logarithms for the finding of $\log(a+b)$ from $\log a$ and $\log b$ [LOGARITHMS, GAUSS'S], with a specimen. He stated that he had been in the habit of using five-figure tables of his own construction. Gauss has given a short review of Pasquich's tables (mentioned below, 1817) in the 'Göttingen gelehrte Anzeigen,' 1817, No. 158.

(1814). [Printed by] Firmin Didot, Paris. Six-decimal logarithms beautifully printed: numbers 0 (1) 21750; sines and tangents 0 (1′) 45°; $x \div \sin x$ and $\tan x \div x$ to 3°; sines, cosines, tangents, cotangents, 0 (0°·00001) 0°·03000 (0°·0001) 0°·5000.

1814. Barlow's Tables, London. Here are found eight-figure hyperbolic logarithms up to that of 10,000, calculated from the primes in Vega. They had been previously printed in Rees's Cyclopædia.

The factors, primes, &c. in this work have been already mentioned, and it also contains a table for the irreducible case of cubic equations, binomial coefficients, algebraic formulæ, specific gravities, &c. The reprint of 1840 contains only the squares, cubes, square and cube roots and reciprocals; but for these things it is the most accurate which exists.

1817. Thomas Preston, 'A new system of Commercial Arithmetic.' Sets of five-figure logarithms. In the first, the number is *also* represented as a number of pence, and turned into pounds, &c. Thus, 9701 has 40*l.* 8*s.* 5*d.* on the other side of its logarithm: this is carried as far as 130*l.* A similar table for avoirdupois pounds, as far as 5 tons. A table from 1 to 330, proceeding by twelfths: from 1 to 312, by sixteenths: and other tables of the same kind. This is one of the largest attempts of the kind.

1817. J. Pasquich, 'Tabulæ Logarithmico-Trigonometricæ contractæ,' Leipzig. Title and explanations in both Latin and German. Five-decimal logarithms of numbers 0 (1) 10,000; logarithms of sines and tangents 0 (10″) 56 (20″) 1°; five-decimal logarithms of sines and tangents, with a table of the *squares* of sines and tangents 0 (1′) 45°; *Gauss's Logarithms.* [LOGARITHMS, GAUSS'S.] The range of A is as follows, 0 (·001) 2 (·01) 3·40 (·1) 5. This trigonometrical canon of squares is, we suppose, almost unique.

1817. [E. A. Matthiessen], 'Tabula ad expeditiorem Calculum Logarithmi Summæ vel Differentiæ duarum Quantitatum,' Altona. It is to seven decimals, and A proceeds as follows: 0 (·0001) 2 (·001) 3 (·01) 4 (1) 5 (1) 7. But having only four figures of argument, the seven figures of tabular result are very troublesome to deal with, and the arrangement is not commodious. Gauss, in a letter to Schumacher, (September, 1846) writes as follows: (translated) "The English edition (referring to Mr. Peter Gray's work of 1849, then in progress) will no doubt correct the deficiencies which make Matthiessen's edition nearly useless. My tables are intended to make computation which can be made *without their help*, more *commodious* by their help. You must not have trouble to find what is to come out of the table, but you must find it in the most easy manner possible. This is not the case with Matthiessen's table, as I have shown in No. 474 of the 'Astron. Nachr.' There is another excess to be avoided: Matthiessen had not done enough. There is a parsimony of number."

(1818). Gruson's 'Logarithms,' Berlin. Contains also squares, cubes, square roots, and cube roots up to 1000.

1821. Nordmann, 'Adriani Vlacq Tabulæ,' &c. The explanations are given in Latin and German. To the contents of Ebert's edition (see 1808) are added square and cube roots to seven decimals for all integers up to 1000, the sines and tangents of the first degree being omitted. The form of the canon is modernised, and made completely semiquadrantal. This is called the *twentieth edition*, which very likely it is; but it was the editor's duty to have stated what the other nineteen editions were.

(1821). Westphal's tables, Leipzig, contain Gauss's tables, to five decimals, with proportional parts. (Schumacher)

1823. E. A. Matthiessen, 'Gemeine Logarithmen,' &c., Altona. *Stereotyped.* This table has five-figure logarithms from 1 to 10,000, with a supplemental table of proportional parts, arranged on the two sides of a folding sheet, on canvass.

1827. Babbage, 'Tables of Logarithms,' London. *Stereotyped.* Seven-figure logarithms of numbers only, now exceedingly correct. Printed on various coloured papers; Callet's stereotyped sines were at first printed on yellow paper in France to accompany them; but the French paper was of so bad a colour, that we believe the experiment was not continued. The tirage of 1831 is called a second edition, and copies on tinted paper are met with. In the preface are some conclusions as to the conditions of legibility, the results of trial, which are well worthy the attention of those who have tables to print. Mr. Babbage was, so far as we remember, the first who distinguished an augmented last figure from an unaugmented one: writing the contraction of ·12346 for instance, as $\cdot 123\dot{5}$. This example is now frequently followed. It secures an extreme nicety in certain rarely occurring cases: but we never found any practical balance to the inconvenience of a new symbol, except when the augmented figure is $\dot{5}$. We should recommend that an augmented 5 (Babbage's $\dot{5}$) should be printed v or V: all the advantage of an excellent but over-adopted suggestion would thus be received.

(1827). Salomon, 'Tables de Logarithmes,' Vienna. A large collection: contains also squares, cubes, square roots, cube roots, up to those of 1000; and divisors up to 102,011.

1827. Hantschl's Tables, Vienna. Ten-figure logarithms of primes up to 15,391; squares, cubes, square and cube roots, up to those of 1200; factors up to 18,277; and others.

1827. G. F. Ursinus, 'Logarithmi,' &c., Copenhagen. A complete six-figure table: rather common in England.

1828. Encke's four-figure Tables of Logarithms, &c., Berlin, contain Gauss's tables. See '1845, Warnstorff,' &c. below.

Logarithmen von vier Decimal-Stellen Berlin, 12mo. Four-figure logarithms, 0 (1) 1000, 0 (10′) 45°, without any name, letter-press, or date.

1829. Bagay, 'Nouvelles Tables Astronomiques,' Paris. An imitation of Michael Taylor's, logarithms of sines and tangents to every second. The logarithms of numbers are 0 (1) 21600. All to seven decimals.

1830. Hassler, 'Logarithmic, &c. Tables,' in a pocket form, New York. Seven-figure logarithms throughout: to half-minute intervals through the greater part of the tables of sines, &c. The logarithms of numbers broken as in Callet. We dislike this mode extremely; but many find it convenient.

1831. Lalande, 'Tables de Logarithmes,' Paris. *Stereotyped* in 1805; 1831 is the date of the first *tirage* with all corrections made. Five-figure tables throughout, and no mistake has ever been found in them, though it is said a reward was offered for any detection. There are, we believe, Brussels and other editions which have not the same character. The original work of Lalande, or Lacaille, Lalande, and Marie, had six places; last edition 1804; there was another, bearing the name of Lalande only, stereotyped in 1804. A similar table, with *seven* decimals, has been published for the use of students preparing for the Polytechnic School, and is sometimes furnished for the genuine Lalande: it is useless for ordinary purposes. If the English reprint of the tirage of 1831 (presently noted) be as correct, and no error has yet been found, it is much the better by type and paper.

1832. J. P. Gruson, 'Bequeme Logarithmische . . Tafeln,' Berlin. A school-book. Seven-decimal logarithms 0 (1) 10,000; squares and cubes, square and cube roots 0 (1) 1000; arcs of the circle; sines and tangents and their logarithms 0 (1′) 5° (10′) 45°.

1832. H. G. Köhler, 'Tables de Logarithmes,' &c. An edition of Lalande which gives Gauss's logarithms.

No date, (stereotyped,) Moritz von Prasse, 'Logarithmische Tafeln,' edited by Mollweide, and then by Jahn, Leipzig. Five-decimal logarithms of numbers 0 (1) 10,000; of sines and tangents 0 (1′) 45° put together in a new way, so as to separate the common figures, as in the logarithms of numbers, and to get five degrees into a double page, sacrificing the differences; Gauss's Tables, A having 0 (·001) 2 (·01) 3·40 (·1) 5; and a modification of Gauss's table, in which $\log x$ is the argument, and $\log\left(\frac{x-1}{x+1}\right)$ the tabular result, x going through ·382 (·001) 5 (·01) 3·6 (·1) 5·5. An edition of Von Prasse was published by Halma, at Paris, in 1814; and the last-mentioned table was published separately by Wiedenbach, Copenhagen, (1829).

1834. Robert Wallace, 'Mathematical Calculator,' Glasgow. Six-figure logarithms, with other tables. The trigonometrical tables arranged by double entry for tens and units of minutes.

1836. Anonymous (Simpkin, Marshall, and Co.), 'Logarithmic Tables.' A very neat reprint of Hassler without the (to us) objectionable breaking of the lines in the logarithms of numbers.

1838. G. B. Airy, 'Appendix to the Greenwich Observations, 1837,' London. A table of sines and cosines, with the arguments given in *time*, $0\ (10^s)\ 24^h$ and the signs marked. There is a separate table both of sines and of cosines, each of which is therefore a transformation of the other. And each again is the table from 0 to 6^h repeated, with transformation, four times; so that the pair of tables is an eight-fold repetition of one table. It is to five decimals, without differences.

1839. Anonymous (Taylor and Walton, under Useful Knowledge Society; suggested by Mr. De Morgan; examined by Mr. Farley). *Stereotyped.* A reprint of Lalande (*tirage* of 1831) with a few additions, closely compared with other tables. No error was found in Lalande, and none has hitherto (1861) been found in this reprint. The old numeral type was first completely restored in this work.

After the first *tirage*, the following addition was made:—One page, for example, begins and ends with the numbers 5220 and 5310, and with the logarithms ·71767 and ·72509. According, at the corner of the page, so as to catch the eye on opening the book, is

5220	·71767
5310	·72509

in full. This plan ought to be adopted in all tables, instead of the abbreviations which are frequently employed as headings, unless the plan be adopted which is recommended at the beginning of this article.

1840. Anonymous (Taylor and Walton), Four-figure logarithms on a card. *Stereotyped.* Reprint of a table originally privately circulated among practical astronomers. (See 'Companion to the Almanac' for 1841.)

1842. Sines and tangents to match. Stereotyped.

1840. Farley, 'Six-figure Logarithms,' London. Stereotyped. An excellent table for those who want six figures. The type as in the reprint of Lalande (1839). The whole was suggested by the late Mr. Galloway.

1840. (Second edition.) Moritz Rühlmann, 'Logarithmisch-Trigonometrische . . . Tafeln,' Dresden and Leipzig. Six-decimal logarithms of numbers 0 (1) 10080; logarithmic sines and tangents 0 (1′) 45°; sines and tangents 0 (10′) 45°; arcs and circles.

(1840.) Hülse's edition of Vega. Leipzig, stereotyped. This contains Gauss's tables to five decimals with proportional parts, in six columns, the additional three (which contain a peculiar mode of treating the proportional parts) having been also suggested by Gauss. A more recent tirage of this excellent work, 1846, contains seven-decimal logarithms of numbers 0 (1) 108000; logarithmic sines and tangents 0 (0″·1) 1′ (1″) 1° 32′ and 0 (10″) 6° (1′) 45°; angles to eleven decimals; five-decimal Gauss's tables, A being 0 (·001) 2 (·01) 3·4 (·1) 5; with the proportional parts above alluded to.

1841. Gregory, Woolhouse, and Hann, 'Tables for Nautical Men.' Contains five-figure logarithms, neatly printed; the only instance we know in which five-figure logarithms have proportional parts. There are many astronomical tables.

1841. Riddle, 'Tables,' &c. The six-figure logarithms from Mr. Riddle's well-known work on navigation. *Stereotyped.*

Of the misuse of tables, no instance is more common than that which consists in taking tables of too many places of figures. Four are very often enough, more than five are rarely wanted; but when this happens, tables of seven figures are more conveniently used than those of six, owing to the saving of calculation which is made by the presence of proportional parts. In purely trigonometrical calculations, the advantage of six figures over five sometimes makes itself apparent. It is our own practice, when five figures are suspected to be insufficient, to have recourse to seven at once, which we are satisfied is a saving both of time and thought. For navigation, however, practical opinion seems to set in favour of six figures.

1845. Warnstorff's edition of Schumacher's 'Sammlung von Hülfstafeln' (first published in 1822), Altona. This is a well-known and valuable astronomical collection. What we have here to do with is the republication of Encke's four-figure logarithms, 0 (1) 1000, and 0 (4′) 10° (10′) 45°, and Gauss's logarithms 0 (·01) 1·80 (·1) 4.

1846. R. Sheepshanks, 'Tables for facilitating Astronomical Reductions,' London (also issued two years before, without title, preface, or author's name). This is the most complete *four-figure* table we know of, and will do for the purpose oftener than our orthodox septenarians are aware of. Logarithms 0 (1) 1000, with proportional parts, in decads; logarithms of sines and cosines, *the angle being in time*, 0 (1^m) 24^h, with proportional parts for 10^s, and 0 (10^s) 1^h; table for converting sidereal into mean solar time; logarithmic sines, tangents, and secants 0 (1′) 6° (10′) 45°; constants for precession; tangents and secants 0 (10′) 80° (1′) 86° (1°) 90°; with a rule for the rest; Bessel's refractions; Gauss's tables, thus arranged, log x as an agument gives log $\left(1+\frac{1}{x}\right)$ as a tabular result, and log $\left(1-\frac{1}{x}\right)$ as another, log x being 0 (·001) ·909 (·01) 2 (·1) 4 in the first table, and 0 (·001) 1 (·01) 3 (·1) 4 in the second; log. $\sin^2 \frac{1}{2}$ hour angle, in time 1^h (1^m) 9^h; numbers to logarithms 0 (·001) 1.

1846. G. F. Vega, 'Logarithmisch-Trigonometrisches Handbuch.' Leipsic: edited by J. A. Hülsse; 0 (1) 108000, logarithmic sines and tangents 0 (0″.1) 1′ and 0 (1″) 132, the whole canon 0 (10″) 6° (1′) 45°, all to seven decimals. Gauss's table to five decimals: for A, 0 (·001) 2 (·01) 3·4 (1) 5, with proportional parts.

Among the titles of tables which we might have said something on if we had seen them, collected from different sources, are those of—John Lauremberg, Leyden, 1628, 8vo.; Institutio Mathematica, London, 1661, 12mo.; Strauchius, Witteberg, 1662, 12mo., and Amsterdam, 1700, 8vo.; D. R. Van Merop. Harlingen, 1671; Chr. Grüneberg, Tabulæ Mathem., Berlin and Frankfort, 1690 (oblong form); Chr. Grüneberg, Pandora Mathem., Berlin and Frankfort, 1700, 8vo.; Chr. Wolff, Magdeburg, 1711, 8vo.; J. G. Leibknecht, Giess, 1726, 8vo.; Raph. Levi, Hanover, 1747, 4to., and supplement in 1748; J. C. Nelkenbrechers, Leipzig, 1752, 4to.; J. Melitaõ da Mata, Lisbon, 1790, 8vo. We have a table of which the title is torn out, but at the back is 'Coloniæ, 1649.' We suppose it to be the table which we have seen ascribed to Lubert Middendorff, Cologne, 1648. It is of seven decimals, 0 (1) 10000 and 0 (1′) 45°: and to the logarithms of sines, cosines, and tangents are added the tangents themselves, to three decimals.

1849. Lieut.-Col. Robert Shortrede's 'Logarithmic Tables,' Edinburgh, large 8vo. The whole of these tables were constructed and stereotyped by the labour and at the expense of Colonel (then Captain) Shortrede, of the Bombay army, attached to the trigonometrical survey of India. They first appeared in 1844; but, some defects and errors having been found, the edition of 1844 was cancelled, and a new edition, from corrected plates, issued in 1849. The whole is to seven decimals, and contains: logarithms of numbers 0 (1) 120,000, with differences and their nine multiples; numbers to logarithms ·00000 (·00001) ·99999, with the same; trigonometrical tables *to every second*, with arguments and signs for the four quadrants, both in space and time, and proportional parts. There are also some minor tables. The type is a small even figure, without head or tail, good of its kind, and the same throughout the common and the trigonometrical logarithms. This is, so far as we know, the only set of tables to every second undertaken at the expense of an individual, and it shows extraordinary energy and public spirit.

1849. P. Gray, 'Tables and Formulæ for Life Contingencies,' London. The tables are Gauss's tables, giving log $(1+x)$ where log x is 0 (·0001) 2, and log $(1-x)$ where log x is $\bar{3}$ (·001) $\bar{1}$. The proportional parts are to hundredths.

1849. H. E. Filipowski, 'A Table of Antilogarithms,' London. Five figures of logarithms to seven of number; proportional parts carried to hundredths. Also, Gauss's tables, on a new mode of arrangement.

1850. Hershell E. Filipowski. A table of five-figure logarithms 0 (1) 10000, all on one side of a sheet. The object is effected by help of common figures at the tops of columns; but before we could use the table rapidly, there must be horizontal ruling, and vertical painting of the columns, with regions of different tint to distinguish the logarithms of different second figures. This being done, a person of sharp sight might really have the whole within his grasp without turning a leaf. A common table, with indented margin, as described at the beginning, would find the logarithms far more rapidly. The necessity of dispensing with printed differences is alone almost fatal to the attempt at giving five-figure logarithms on one sheet.

1850. Zacharias Dase, 'Tafel der natürlichen logarithmen,' Vienna. Hyperbolic logarithms to seven decimals 0 (1) 105000, arranged, with proportional parts, in the common way. Mr. Dase is a mental calculator, and, having seen his performances, we think he has more natural power than any of those who have distinguished themselves in this way.

1853. William Shanks, 'Contributions to Mathematics, comprising chiefly the rectification of the Circle to 607 places of tables,' London, 1853. [QUADRATURE OF THE CIRCLE.] Here is a *table*, because it tabulates the results of the subordinate steps of this enormous calculation as far as 527 decimals; the remainder being added as results only during the printing. For instance, one step is the calculation of the reciprocal of 601. 5^{601}; and the result is given. The number of pages required to describe these results is 87. Mr. Shanks has also thrown off, as chips or splinters, the values of the base of Napier's logarithms, and of its logarithms of 2, 3, 5, 10, to 137 decimals; and the value of the modulus ·4342 . . . . to 136 decimals; with the 13th, 25th, 37th, ... up to the 721st powers of 2. These tremendous stretches of calculation—at least we so call them in our day—are useful in several respects: they prove more than the capacity of this or that computer for labour and accuracy; they show that there is in the community an increase of skill and courage. We say in the community: we fully believe that the unequalled turnip which every now and then appears in the newspapers, is a sufficient presumption that the average turnip is growing bigger, and the whole crop heavier. All who know the history of the quadrature are aware that the several increases of numbers of decimals to which π has been carried, have been indications of a general increase in the power to calculate, and in courage to face the labour.

Here is a comparison of two different times. In the day of Cocker, the pupil was directed to perform a common subtraction with a voice-accompaniment of this kind: "7 from 4 I cannot, but add 10, 7 from 14 remains 7; set down 7 and carry 1; 8 and 1 which I carry is 9, 9 from 2 I cannot, &c." We have before us the announcement of the following *table*, undated, as open to inspection at the Crystal Palace, Sydenham, in two diagrams of 7 ft. 2 in. by 6 ft. 6 in. "The figure 9 involved into the 912th power, and antecedent powers or involutions, containing upwards of 73,000 figures. Also, the proofs of the above, containing upwards of 146,000 figures. By Samuel Fancourt, of Mincing Lane, London, and completed by him in the year 1837, at the age of sixteen. N.B. The whole operation performed by simple arithmetic." The young operator calculated by successive squaring the 2nd, 4th, 8th, &c., powers up to the 512th, with proof by division. But 511 multiplications by 9, in the short (or 10—1) way, would have been much easier. The 2nd, 32nd, 64th, 128th, 256th, and 512th powers are given at the back of the announcement.

The powers of 2 have been calculated for many purposes. In vol. ii. of his 'Magia Universalis Naturæ et Artis,' Herbipoli, 1658, 4to, the

Jesuit Gaspar Schott having discovered, on some grounds of theological magic, that the degrees of grace of the Virgin Mary were in number the 256th power of 2, calculated that number. Whether or no his number correctly represented the result he announced, he certainly calculated it rightly, as we find by comparison with Mr. Shanks.

1853. A. Wylie, 'Compendium of Arithmetic,' Shang-hae. A treatise in Chinese, having at the end a table of six-decimal logarithms of numbers 0 (1) 10,000.

1856. J. R. Hind. Natural versed sines . . . . used in computing lunar distances for the 'Nautical Almanac.' This table gives natural and logarithmic versed sines to seven decimals: natural, 0 (10″) 125°, with the proportional parts for each second; logarithmic, 0^h (1^s) 9^h, with the values of the angles in space annexed. This table, though bearing in its title only a limited notion of application, will be exceedingly valuable, especially to those who want sines, cosines, and their squares.

1857. George and Edward Scheutz, 'Specimens of tables calculated, stereomoulded, and printed by machinery,' London. The first production of the machine which two Swedes, father and son, constructed on Mr. Babbage's principles, as suggested by Dr. Lardner's article in the 'Edinburgh Review' (1834), with their own details; five-figure logarithms 0 (1) 10000; with some specimens of other tables. This work was reproduced at Paris, with a French preface, in 1858. In 1859, was published 'Mountain Barometer Tables,' calculated by the same machine.

1859. Edward Sang, 'Five-place logarithms,' 0 (1) 10000.

1860. Ludwig Schrön, 'Schrön's Logarithms,' Tafel I., II., III. We had just, as we thought, put the finishing hand to this article, when the table above-named reached us. Should it turn out to possess the requisite accuracy of printing, it will have decided success. It is a large octavo volume of 550 pages of tables. The type, though without heads and tails, is all as nearly as possible of one thickness, and that thickness not too great, so that it might be called *thin Egyptian;* and it is very legible. The contents are all to seven decimals. Logarithms of numbers 0 (1) 108000, with subsidiary tables at the bottom of the page, which by addition of two logarithms in the page give the logarithms of sines and tangents, 0 (0″·001) 1″ (0″·01) 10″ (0″·1) 1′ 40″ and 1′ 40″ (0″·01) 16′ 40″ (0″·1) 3°. Logarithms of sines and tangents, 0 (10″) 45°. The differences begin to be inserted from 3°; and the first nine multiples complete, that is, one figure more than in the common table of proportional parts, are given in the same page; first for every fifth number, then for every three, &c., as the page will bear it. Under 3° multiples of subsidiary numbers are given, as explained. Then follows a table of proportional parts to complete hundredths, for numbers from 40 to 409.

1860. Galbraith and Haughton, 'Manual of Mathematical Tables.' The usual five-figure table, with Gauss's table, A 0 (·001) 2 (·01) 3·39 (·1) 5. The first British five-figure table, we believe, which gives Gauss's table.

1861. A. De Morgan. Three-figure logarithms: three figures of number to three of logarithm, complete, on a sheet of 7½ by 6 inches. The third figure of the number in every case by the side of the logarithm: all numbers in red, logarithms in black. The *quarter* of a unit in which the logarithm lies, shown by use of the four common punctuating stops. Intended for the earliest instruction in logarithms, and as a substitute for the sliding rule in certain cases.

§ 7. The next tables which we shall mention are those which are wanted in the higher mathematics.

Extensive tables of *elliptic functions* are in Legendre's 'Traité des Fonctions Elliptiques,' 2 vols. 4to., 1825 and 1826. The *factorial* function, Γx, is tabulated in the same work; and also in the 'Exercices du Calcul Integral' of the same author, Paris, 1817, in which several other definite integrals are also tabulated. An abridgment of this table (with ready means of restoring it fully) is in the treatise on the Differential Calculus ('Lib. Use. Know.'), p. 587. Tables of the integer form of Γx, or $1.2.3 \ldots (x-1)$, or rather of the logarithms of the values, are given by C. F. Degen, 'Tabularum Enneas,' Copenhagen, 1824, up to $x = 1201$, to 18 decimal places: this table is reprinted to six decimal places at the end of the article 'Theory of Probabilities' in the Encyclopædia Metropolitana. Tables of the integral $\int \epsilon^{-t^2} dt$ were first given by Kramp, with logarithms of the values, in 'Analyse des Refractions Astronomiques,' Strasburg, 1799. This table is reprinted in the Encyc. Metrop., art. 'Theory of Probabilities.' The form in which this integral more usually occurs in the theory of probabilities (with the factor $2 : \sqrt{\pi}$) was given (by Professor Encke, we believe) in the Berlin 'Astronomisches Jahrbuch' for 1834, from whence it was copied into the article in the Encyc. Metrop., above noticed; and (with extensions) into the 'Essay on Probabilities and Life Contingencies' in the Cabinet Cyclopædia, and into the article on Probability in the new edition of the 'Encyclopædia Britannica.' A few other definite integrals have been tabulated: one very useful one, $\int dx : \log x$, by Soldner, 'Nouvelle Fonction Transcendente,' Münich, 1809, copied into the 'Differential Calculus' ('Lib. Use. Know.'), p. 662. The integrals known by the name of Spence's *Logarithmic Transcendants*, are in the work with that title (Edinburgh, 1809; Sir J. Herschel's edition, London, 1820). There are a few of the integrals in optics scattered through the Memoirs of the Institute and of the Cambridge and Philosophical Society (in memoirs by Fresnel and Mr. Airy). Perhaps we should also mention the tables for the solution of indeterminate equations of the second degree. Of these there is one in Legendre's 'Théorie des Nombres;' another has been given by Jacobi; and a third, by Degen, called 'Canon Pellianus,' Copenhagen, 1817.

There is much need of tables of mathematical results which are not numerical; such as the following, the only ones of which we are able to speak. The first, the well-known collection of indefinite integrals by Meier Hirsch, 'Integral tafeln,' Berlin, 1810, of which an English edition was published in 1823, 8vo. The second, a table of definite integrals, with reference to their sources, by Bierens de Haan, 'Tables d'Intégrales définies,' being the fourth volume of the 'Amsterdam Transactions,' Amsterdam, 1858.

As to astronomical tables, it would be impossible to give any account of the enormous mass which exists or has existed; nor would such an account be of any use, except for astronomical history. They may be divided into two classes: first, the tables of observations published by public or private observatories; secondly, the fundamental tables deduced from observations, to aid in the deduction of future predictions. As to the former, every well-conducted observatory in full work publishes periodically (at intervals of one or two years) its volume of observations, latterly with their reductions. As to the second class, they are not the daily materials of the astronomer, but of the computer of his ephemeris, who supplies the necessary predictions for the current year. In England the Nautical Almanac gives in the preface full references to the tables employed in predicting places, whether of sun, moon, planets, or stars. For general purposes connected with the elements of the solar system, see Baily, 'Astronomical Tables and Formulæ,' London, 1827. The most complete list of the elements of the solar system recently published is at the end of Dr. Mitchel's 'Popular Astronomy' (U.S.), and also of Mr. Tomlinson's English edition of the same work.

The tables in the other physical sciences are mostly collections of facts, and, we believe, generally speaking, by no means so complete as they might be. The value of tabular information seems to be not sufficiently felt. A large portion of every book of chemistry, for instance, is a detailed statement in words at length of facts which might with great advantage be made the components of a table.

§ 8. It remains to speak of commercial tables, a subject of great interest in this country, which has produced a great many. The mathematical tables connected with this subject may be divided into those intended to facilitate calculations of money with regard to other countries, and with regard to transactions in this country; to which we must add, as distinct heads, tables of annuities and other life contingencies, and metrological tables, or tables of weights and measures. Of all these we shall only mention a very few.

The most complete work on foreign exchanges, and on the weights and measures of England, as compared with those of other countries, is 'The Universal Cambist,' &c., London, 1821 (2nd edition), 2 vols. 4to. (with supplements), by the late Dr. Patrick Kelly. We may also mention Tiarks's 'Arbitration of Exchanges,' London, 1817.

Tables of interest of money begin with Stevinus, who in the 'Practique d'Arithmetique,' appended to his Arithmetic, Leyden, 1585, reprinted by Albert Girard in Stevinus's collected works, 1626, gave the first tables of compound interest and annuities. They precede the famous tract 'La Disme,' in which decimal fractions were first proposed. And as this *Practique* should rather have been at the beginning than at the end, if rational arrangement had been studied; and as the 'Disme' again should have preceded it, on the same supposition; we must infer it to be most likely that the tracts were placed in the order in which they were written. If this be the case, then it is pretty certain that these tables of compound interest *suggested decimal fractions*, the account of which speedily follows them. They are constructed as follows:—Ten millions being taken as the base (or *root*, as Stevinus calls it), and a rate, say five per cent., being chosen, the present value of ten millions due at the end of 1, 2, &c., up to 30 years, are put in a column, to the nearest integer. By their sides are the sums of their values, which give the present values of the several annuities of ten million, as follows:—

Table d'Interest de 5 pour 100.

1	9523810	9523810
2	9070295	18594105
3	8638376	27232481
4	8227025	35459506
. . .	. . . .	. . . .
. . .	. . . .	. . . .
30	2313774	153924494

The rates are from 1 to 16 per cent., and also for 1 in 15, 1 in 16, &c., to 1 in 22; or, as the French say, *denier quinze, denier seize*, &c. At the end is a direction to dispense, when convenient, with some of the last figures.

There is thus a virtual use of decimal fractions preceding the formal one. The same thing happens in the tables of Richard Witt, presently mentioned, which we believe to be the first English tables of compound interest, and the first English work (except a translation of the 'Disme' of Stevinus) in which decimals were used: the use of them being something more than the virtual use by Stevinus in the 'Practique.' The next English writer who gave tables of compound interest, Robert Butler, in his 'Scale of Interest,' London, 1633, makes a rather more decided use of these fractions than Witt, and uses the phrase *decimal fractions*, which had then hardly found its way into books. It should be noted that both Witt and Butler give real half-yearly and quarterly tables, as well as yearly ones.

Tables of interest began to be published at the beginning of the 17th century. The earliest we have met with is Richard Witt, 'Arithmeticall Questions,' London, 1613, which, before the introduction of the notation of decimal fractions, gives tables, or *breviats*, containing the significant figures, with rules equivalent to the management of the decimal point; and Clay's 'Briefe, &c., Tables,' London, 1624. In the first half of that century we find in catalogues the works of Fisher, Butler, Webster, and others, with anonymous writers, all containing tables of interest, annuities, or leases. For the tables known by the name of Æcroid, see MORTALITY. The tables of leases, Cambridge, 1686, had the approbation of Newton, as Lucasian professor, and have since been often reprinted and styled Newton's.

Mr. Pocock, in his Bibliography of Annuities, &c. ('Familiar Explanation . . . . of Assurances upon Lives,' London, 1842), gives the following works, which we do not remember to have seen:—'Tables of Leases and Interest . . . ,' London (1628), 12mo.; and William Purser, 'Compound Interest and Annuities, containing the Art of Decimal Arithmetic,' London (1634), 8vo.

In Newton's 'Scale of Interest,' mentioned in the list of logarithms, is a set of tables for six per cent., then the maximum legal rate. There is here what we never met with elsewhere—a common almanac, with months, dominical letters, and fixed saints' days; having, in lieu of astronomical information, simple and compound interest and discount tables, telling for each day the amount of one pound from the beginning of the year, or the present value for the end.

The first edition of Smart's tables, the original of all our large tables of compound interest, is 'Tables of Simple Interest and Discount, at 3, 4, 5, 6, 7, 8, 9, and 10*l.* per cent. per Ann.; also Tables of Compound Interest at the same rates, whereby,' &c. By John Smart, at the Town Clerk's Office, London: London, 1707, 4to (duodecimo size). The second edition, of 1726, is as large, compared with the first, as it is possible its author, "John Smart of Guildhall, Gent.," may have become, compared with the subordinate at the town clerk's office. It adds 2½, 3½, and 4½ per cent. The results are interpolated for half years, which give the tables the appearance of being calculated for interest payable half-yearly; but the fact is that yearly payments are supposed. A second edition of this work, enlarged, by C. Brand, London, 1780, has the reputation of containing many errors. The first edition (which we did not know of when we first wrote, and we find all * modern writers knew as little), besides a smaller range of rates, has not the half-years, and has only six decimal places. The tables of simple interest are also of very little extent. This set of tables was incorporated (with acknowledgment) in the article 'Interest' in the second volume of Harris's 'Lexicon Technicum,' London, 1710. There was an abridged edition, with some of the rates and of the half-years left out, but still to eight figures, 'Tables of Interest, &c., abridged for the use of Schools, in order to instruct young gentlemen in the use of Decimal Fractions,' by John Smart, &c., London, 1736, quarto (octavo size).

Mr. Baily's 'Doctrine of Interest and Annuities,' London, 1808, is as extensive as Smart's for whole years, and as correct; and the 'Tables of Leases,' London, 1807, by the same author, contain the simple cases which the name implies, tabulated by themselves. The 'Doctrine of Interest,' by Francis Corbaux, London, 1825, contains the real distinction of yearly, half-yearly, and quarterly interest: these tables are repeated in the same author's work on 'Population,' London, 1833. Mr. Hardy's 'Doctrine of Simple and Compound Interest,' London, 1839, contains rates of interest increasing by ¼ per cent. from ¼ up to 5 per cent., with succeeding integer rates. All the standard works on life annuities contain tables of compound interest.

There seems to have been a tendency at the beginning of the last century to publish commercial tables in copper-plate, probably with a view to secure the advantage which stereotype has since secured in a better form. Thus we have the "arithmeticall tables" of C. Bardon (Roy. Soc. library) without date; Lostau's 'Manual Mercantile,' second book (first never published), London, 1733; Rev. G. Brown's 'Arithmetica Infinita, London, 1717; the two last being multiplication tables, with multiples of numbers and fractions useful in money transactions, arranged under heads. The following may be mentioned as containing hints which might even now be useful:—Benjamin Webb, 'Tables for Buying and Selling Stocks,' London, 1759; also 'The Complete Annuitant, or Tables of Interest,' London, 1762; Hayes's 'Moneyed Man's Guide,' a table for computing dividends, London, 1726. The French have a large number of tables answering to our ready-reckoners, under the names of *Barême* (a word of the same use with them as Cocker with us), *comptes-faits*, &c. We have seen one of them of the decimal character, in which a metal plate with rectangles pierced in it serves, on one rectangle being placed over the integers of the number given, to make another separate those of the number to be found.

Commercial tables of any real power are rendered impossible in practice by the use of shillings, pence, and farthings, except by an extent of matter which makes them very expensive. If, indeed, the rule for decimalising the parts of a pound [COMPUTATION] were well learned and properly used, some of the older tables, which have fallen entirely into oblivion, would certainly be revived with effect. Two of those presently mentioned will certainly be reprinted when the time comes; Brown's 'Arithmetica Infinita,' and Webb's 'Tables for Buying and Selling Stocks.' The main part of the former is the first nine multiples of the decimal, which expresses any number of farthings in a pound. Thus, under 7*s.* 8½*d.* are ·3854166 . . . and its multiples up to nine times. The latter has the multiples necessary to find the quantity of stock which answers to any sum of money, and *vice versâ*, at different prices. These are both pocket tables, and their places are supplied at present by works of much greater bulk and less extensive use.

We now give a very condensed account of a few mercantile tables. We take them merely because we happen to have examined them, without any selection. Such a list, meagre as it is, both in amount of works and in description, may be of much use to one who is contemplating the construction of a table. He may be warned that tables exist which he should consult before he settles his plan; for those we have quoted may suggest the expediency of looking out either for themselves or for others resembling them; or he may receive a hint even from so brief a description as ours. There will appear, in so short a list as this, sufficient evidence of the never-ceasing attempt to bring decimal * fractions into tabular connection with our mixed money. There has never been any lasting success with the world at large; and we must continue, in our commercial arithmetic, at perpetual war with our own first principles, until we are wise enough to decimalise our coinage, and ultimately our weights and measures.

In the following list, the letters Q., O., or D., for quarto, octavo, and duodecimo or under (referring to size, and not to mode of printing), precede the date and begin the description of each work:—

O. 1613, London: Richard Witt, 'Arithmeticall Questions;' compound interest. Q. 1619, Leipsic: 'Ein newes metzbar gerechnetes Rechenbuch;' ready-reckoner, tables of multiplication of prices. D. 1629, London (2nd edition, many editions): William Webster, 'Webster's Tables;' small tables of simple interest. D. 1632, London: John Bill, 'Accompts cast up;' ready-reckoner, simple multiplication of integer numbers up to 100 times; the earliest English ready-reckoner we know of. O. 1633, London: Robert Butler, 'The Scale of Interest;' tables of discount and present value. O. 1668, London: John Newton, 'The Scale of Interest' (see Logarithms, 1668). O. 1677, London: Michael Dary, 'Interest Epitomized;' small tables of compound interest; a rare and remarkable book in other respects. D. 1682, Amsterdam: J. Sarfatti Pina, 'De Lichtende Koopman's Fackel;' multiples of money in facilitation of exchanges. D. 1686, Cambridge [Mabbot]: 'Tables for Renewing and Purchasing of the Leases of Cathedral Churches † and Colleges;' reprinted almost down to our own time (to 1808 at least) under the name of Newton, because it has Newton's certificate of approbation of the method. Mr. Edleston, who has found the name of the writer in his researches into Newton's biography, says that he was manciple, a caterer, of King's College. In the treasury of Trinity College, he adds, is a table and explanation, in Newton's handwriting (1674-5), of the fines for renewing years lapsed in a lease for 20 years. It is entitled, 'Tabula redemptionalis ad reditus Collegii SS. Trinitatis accomodata,' and gives seven years' purchase for the whole lease, and one year for seven years lapsed. This allows the lessee upwards of 13 per cent. This table was employed till 1700, when Bentley introduced 10 per cent. tables; but the "greediness for present sealing money" compelled a return to the old system. Dr. Smith, in 1742, reintroduced the 10 per cent. tables, which became 9 per cent. in 1750. Newton's table is published in the 'Journal of the Institute of Actuaries' for January, 1861, vol. ix., No. 42. O. 1693, London: W. Leybourn, 'Panarithmologia . . . . all performed by tables ready cast up;' ready-reckoner, multiples of prices, &c. D. 1707, London: John Smart, 'Tables of Simple Interest . . . . also Tables of Compound Interest;' the first edition of these celebrated tables. D. 1710, London: John Castaing, 'An Interest Book . . . ;' interest per year reduced to days by tables. O. 1711, London: E. Hatton, 'An Index to Interest;' units, tens, and hundreds of pounds principal, reduced to interest for each number of days in the year. D. 1718, ——: Geo. Brown, 'Arithmetica Infinita;' all farthings under one pound reduced to decimals, with the first nine multiples of each (the whole in copper-plate; the figures very rough, as if put in by the author's own hand). Q. 1726, London: John Smart, 'Tables of Interest, Discount, Annuities;' the second edition, and the best. D. 1726, London: Richard Hayes, 'The Money'd Man's Guide;' tables of dividends on sums proceeding by eighths of a pound, at — per cent.

---

* Dr. Farr ('Reg.-Gen. Rep.,' 1844, p. 559) mentions the edition of 1726 as the *second* edition.

* The day after we had written this we came in contact with an extract from the 'Publishers' Circular,' as follows:—"An old copy of Langham's 'Nett Duties and Drawbacks,' digested into an easy method, once the standard authority on the subject, gives us the exact state of the case a hundred years ago, and leaves us in some astonishment that any head, native or foreign, could have mastered the complicated details then necessary for their own safety to be known to importers . . . . Decimals, indeed, appear to have been the delight of the tariff-maker of old, for the charge on every one of the fifty-eight items [of paper] concludes with some such a fraction—occasionally reaching the delicate nicety of 92⅝ hundredths of a penny." This merely means that commercial arithmetic is more of a mere routine than it was, and that a hundred years ago decimal fractions were more cultivated than they are now.

† Later editions of this work are accompanied by a letter on the value of church leases, which was one commencement of a long dispute, giving many pamphlets. (See 'Notes and Queries,' 2nd series, vol. iv., p. 361.) The practice of raising the fines, which had been very much too low, had been growing for some thirty years previously to 1686; and the publication of these tables seems to have been in justification of the rise. Hence the importance attached to obtaining from Newton a certificate of the method, which those interested might have denied. The dispute, which never died, was very warm in 1729–31, when the clergy were threatened with legislative interference, and did actually receive some implied recommendations to desist from the House of Commons. Common sense, however, seems to have found out at last that the clergy, in spite of the augmentations, were making much less of their lands than the laity; and the next phase of this history is that of 1837, in which year the poor divines were threatened by parliament with the loss of the management of their estates, for letting them *too low*. It is not easy to please everybody.

D. 1735, London: Gael Morris, 'Tables for Renewing and Purchasing Leases . . .;' and, with another title-page, tables of simple interest for years, months, and days. O. 1735, London: James Lostau, 'The Manual Mercantile—Second Book;' the first never published. This book is 450 pages of copper-plate; the descriptions, &c., in a professional handwriting; all the table-work in the roughest figure, as if put in by the author for security against error. First nine multiples of numbers up to 1609; reciprocals to seven significants, and first nine multiples, up to 1535; numbers advancing by eighths of a unit, and their nine multiples in decimals from 100 to 140, and then by fourths to 156; reciprocals of the same, with nine multiples; pence and farthings in decimals of a pound, with eight and afterwards seven significants, with nine multiples, up to 140*d.*; the number of times pence and eighths are contained in a pound, in decimals, with first nine multiples, up to 140*d.*; a mass of tables for exchange, commission, reduction of weights and measures, &c. &c., all, or most, having results expressed in decimals, with nine multiples of each. O. 1736, London: John Smart, 'Tables of Interest;' the large tables abridged into a school-book. O. 1756, London (19th edition): John Playford, 'Vade mecum;' ready-reckoner of the modern type. O. 1756, London: ——, 'New Sett of Interest Tables;' small tables, followed by tables of excise on beer and ale, printed on one side only, apparently to allow pasting on a wall, and 'designed for a check on the custom-house and excise officers.'

D. 1759, London: Benj. Webb, 'Tables for buying and selling Stocks;' the chief table is one of numbers increasing by eighths, given in decimals, with nine multiples to each, from 60 to 130; and their reciprocals in the same way. D. 1762, London: Benj. Webb, 'Complete Annuitant;' collection of tables subsidiary to interest, not easy to describe briefly. D. 1766, London (14th ed.; 16th in 1775): Richard Hayes, 'Interest at one view;' interest in the form of the ready-reckoner for months and days. O. 1773, Amsterdam: Nicolas Barreme, 'Comptes-Faits;' an edition of the celebrated French ready-reckoner, which, like ours, consists of multiples of sums of money. The name of Barreme (so spelt in the licence, though now *Barême*) is ingrafted on the French language as a word for mercantile calculation. Our *Cocker*[*] is a jesting allusion; but *Barême* is quite a serious word. O. 1773, Brussels, René Neron, 'Comptes-faits[†] pour les changes;' exchanges between different countries, in the ready-reckoner form. O. 1798, Paris: Blavier, 'Nouveau Barême;' adapted to the change of coinage. Q. 1799, London: John Wilson, 'Tables to facilitate the computation of Interest;' containing the proportion of ·05 for each number of days in the year, with multiples of each fraction up to 100, to nine decimals. All calculations are made for five per cent., and afterwards reduced to the rate given: a very common principle of tables. O. 1804, London: S. Newman, 'Collection of Mercantile Tables;' the ready-reckoner (or *multiple*) principle adapted to prices, lengths, interest, &c. O. 1807, London: Francis Baily, 'Tables for . . . Leases' (second edition; first in 1802): the first separate[*] tables of leases of the modern form. Q. 1808, London: F. Baily, 'The Doctrine of Interest and Annuities;' a well-known work, the tables from Smart. D. 1811, London: Wm. Inwood, 'Tables for . . . Estates . . . and Leases;' the idea, and some of the tables, from Baily. O. 1816, Calcutta: G. M. Anderson, 'The Universal Calculator;' a large ready-reckoner for prices, exchanges, interest, weights and measures, &c. O. 1825, London: Fr. Corbaux, 'The Doctrine of Compound Interest;' tables, with a large introduction of half and quarter rates of interest; the tables are added to the author's work on population, 1833, 8vo. O. 1839, London: Peter Hardy, 'Doctrine of Simple and Compound Interest;' tables, with half and quarter rates of interest. O. 1841, London: Geo. Reid, 'Tables of Exchange;' in the ready-reckoner form, relating entirely to sterling and dollars. D. 1847, London: David Allester, 'Table of Simple Interest, comprised in one page;' this page has an arrangement by which each day is shown at five per cent., with its nine multiples. O. 1847, London: D. Allester, 'Decimal Dividend Tables;' the basis consisting of shillings and pence in decimals of a pound, with the hundred multiples of each. O. 1849, London: James Laurie, 'The Golden Ready-Reckoner;' ready-reckoner by multiples of one share at pounds and sixteenths per share. O. 1857, London: C. M. Willich, 'Interest and Time Commutation Tables;' conversion of five per cent. into any other practical rate by inspection; and conversion of days to run into days which give the same at five per cent. D. 1859, Edinburgh: W. Waterston, 'Manual of Commerce' (2nd edition); a ready-reckoner, combined with interest, dividend, &c., tables, and information of many kinds. O. 1859, London: Feodor Thoman, 'Theory of Compound Interest;' a new disposition of the subject, the tables being the logarithms of amounts, and the logarithms of annuities which one pound will purchase. D. 1859, Halifax: 'Nicholson's Ready-Reckoner;' a good specimen of a class of sixpenny books which are now common.

We cannot pretend to give a technical list of life assurance and annuity tables: anything we could do in this way, in any space we could give, would be professionally useless, and otherwise worse than uninstructive. We may, however, attempt to point out and to illustrate an epoch of activity which commenced about the year 1840, and which still continues. In the year 1838, the chief of the professional tables were in the well-known works of Price, Morgan, Baily, Milne, Griffith Davies, and Finlaison. The extent of tables, as judged practicable, went as far as annuities on two lives, for all ages differing by multiples of five years, at 3, 4, 5, and 6 per cent. Barrett's method, the greatest augmentation of resources which was ever created on this subject by any one person, was not in use for want of sufficient application to acknowledged rates of mortality. Milne's book best represents the laborious character of many computations which are now either reduced to insignificance, or themselves actually tabulated for reference. This valuable work (1815) was published by the author at his own expense, and with a certainty of heavy loss; and no public acknowledgment of his merit was made, even when it had become apparent that he had changed the basis of life-tables, and introduced an important reformation by the only efficient means—the construction of a body of tables competing in extent with those already in use, and beyond challenge as to accuracy of computation. Barrett's method is not[†] noticed by Milne in this work; but it only appeared in Baily's Appendix of 1813, and Milne could hardly have had time, occupied as he must have been with his own work, to have thoroughly examined it, much less seriously contemplated the use of it.

The impulse was given by the Useful Knowledge Society (who however had a colleague, as we shall see), when they brought forward Mr. David Jones, and recommended, almost insisted on, a very[‡] considerable extension of his original plan. The only tables in existence for every combination of two lives had been published by Mr. McKean, in 1837, giving on one large sheet the rates 3, 4, 5, 6 per cent., by interpolation from the Carlisle tables. Mr. Jones (whose work was completed in 1843) gave every combination for 3, 3½, 4, 4½, 5, 6 per cent., both in the annuities, and in Barrett's subsidiary tables; that is, twelve tables for all combinations, instead of four tables[*] for combinations differing by multiples of five years of age: and this far from all. A short account of some of the tables since published will show that the example has been vigorously followed; both as to the completion of things which had been but partially done, and as to the origination of new undertakings.

---

[*] We have endeavoured to find the reason why *Cocker*, or rather the book which Hawkins put out in Cocker's name, should be selected as the type of commercial arithmetic. We trace the allusion to 1756, and no farther back. In that year Arthur Murphy's farce of 'The Apprentice' appeared, in which the old merchant *Wingate* is perpetually eulogising *Cocker's* arithmetic. Wingate and Cocker were two of the best-known books on arithmetic. If the allusion cannot be carried farther back, then the probability will be that Murphy took the names of the arithmeticians with whom he most often came in contact, and used them as described. In that case Wingate would have been our Cocker, if Murphy had chosen to make Cocker his Wingate; and Wingate much better deserved the distinction.

[†] Dedicated to the Duke of Lorraine, in verse, which ends as follows:—

> Grand Prince, sois propice à ma juste demande,
> De mon petit travail daigne accepter l'offrande,
> Et, quittant d'Apollon le stile familier,
> Permét-moi de me dire en stile régulier
> Monseigneur,
> De vôtre Altesse Royale,
> Le très-humble, très-obeissant,
> et très-respectueux Serviteur,
> NERON.

[*] A case arose out of this work which illustrates the varying decisions which prevail in the courts when a single judge decides questions of fact. Baily applied for an injunction against a work in which he held his own work to have been pirated. He produced his own original calculations; and proved that all the misprints and errors of the last figure, by the score, which occurred in the parts of his work in question, occurred also in the alleged piracy. But he could not satisfy the court that a piracy had been committed: he happened to light upon a judge who would have thought it might have been a coincidence, if he had seen his own name growing in mustard and cress. Persons who have reason to fear that their tables will be pirated should lay some special traps for detection: many might easily be suggested.

[†] Milne has made it apparent, in his work, that he had had some difference with Baily, who is not alluded to by name, but only by such phrases as "the last author who has treated on this subject." There certainly had been some disagreement. The Sun Fire Office became also a life office in 1810, and Baily was then consulted by the directors: we suspect that the disagreement, whatever it was, then took place. But by the time Milne published his article on annuities in the Encyclopædia Metropolitana (of which the private copies are dated 1837) much of this feeling had worn off. Baily's name is mentioned, and his merits are judiciously, though coldly, acknowledged: but Milne was not given to strong praise; he neither blew his own trumpet, nor that of anybody else. Of Barrett's method Milne thought highly. Having more than once heard it suspected that he was averse to its use, we give an extract from a letter of his to the writer of this article, dated Nov. 17, 1841, while Jones's work was in progress of publication in numbers. "Many thanks . . . . for the Companion to the Almanac of the Useful Knowledge Society, to which truly useful society we are also indebted for Mr. Jones's tables, which will greatly facilitate calculations."

[‡] We speak from positive knowledge. Mr. Jones, though no way disinclined

In saying that the Useful Knowledge Society first showed the way, in actual print, to the construction of more extensive tables, we should commit great injustice to a most daring and persevering calculator, if we omitted to notice that Mr. Edward Sang could have received no hint from their proceedings. His 'Assurance and Annuity Tables,' Edinburgh, 1841, large folio, give, for one life and 3 per cent., almost every deduction from the Carlisle tables which an actuary could have supposed possible to be wanted. And Mr. Sang worked with his hands[†] as well as with his head. Over and above a table of five-decimal logarithms and antilogarithms, every result in the book has its logarithm attached to it. And with this we have the present values of every annuity and assurance, temporary or deferred, which can be made on one life, at any age, and for any duration or deferment: together with a mass of values and premiums for other cases which we shall not attempt to specify. In 1859, Mr. Sang published a second volume, containing, also for 3 per cent., a body of results on two lives which meet all the actuaries' cases; also with logarithms attached. The offices, and many of the actuaries, were at first inclined to look very coldly upon these magnificent efforts; but, so far as we have observed, we think there is now a disposition to acknowledge their utility: their merit was never denied.

Mr. Jones and Mr. Sang, independently of each other, showed that there was no occasion to be frightened at the notion of *calculating and printing* all the cases of a problem of two lives, or of one life for terms of years: at the time when they began their labours, a routine had been established by the consent of several distinguished writers, which consent caused ordinary calculators to look upon anything beyond the routine as next to impracticable. In 1848, Mr. T. Wigglesworth, in 'Carlisle Probability-Tables of the Logarithms . . . .' London, 8vo., gave the logarithm of the chance of surviving every number of years, at every age, from the Carlisle tables. In 1850, Mr. W. Orchard, in 'Single and Annual Assurance Premiums,' London, 8vo., gave tables for converting the value of an annuity into the single or the annual premium for a corresponding assurance; the necessity for which often arrives in masses of instances together. The rates are 2½, 3, 3½, 4, 4½, 5, 6, and 7 per cent.

In 1850, Mr. H. E. Filipowski, in an appendix to his work on antilogarithms, London, 8vo., gave Carlisle annuities at 3 per cent., for *three* joint lives, for all combinations of quinquennial ages. This is the first table of three lives: nothing more than specimens had been previously published.

In 1851, Messrs. P. Gray, H. A. Smith, and W. Orchard, in 'Assurance and Annuity Tables,' London, 8vo., gave, for the Carlisle tables, at 3 per cent., the premium and the annual premium for every case of survivorship assurance on two lives. In 1850, Mr. W. T. Thomson, of the (Scotch) Standard Life Assurance Company, published, in fifteen[‡] sheets, meant to be joined in one, what we may describe as, for the Carlisle tables at 3 per cent., a collection of Barrett's tables, one for each age in the tables: or the number living at every age of life discounted to every lower age. This table might have had its use, if Mr. Thomson himself had not superseded it, in 1858, by his *book*, entitled 'Actuarial Tables, Carlisle Three per cent.,' Edinburgh, 8vo., giving the ultimate elements of the old form of calculation: that is, the present value and logarithm of every year of annuity, and the logarithm of the risk of death in each year, from and after every age. These values are put together in successive sums so that the present value of every deferred annuity, and of every deferred and temporary assurance, is gained directly from the table. A complete table of probabilities of living, logarithms and primitives both, is also given; with some other tables. In 1858, Mr. David Chisholm, in 'Commutation[*] Tables for Joint Annuities and Survivorship Assurances, based on the Carlisle tables at 3, 3½, 4, 5, and 6 per cent.,' London, 2 vols., 8vo., introduced, in addition to Barrett's tables for two joint lives, the form for survivorship assurances, by which such assurances for terms of years, or when deferred, are immediately calculated. There are other efforts with which we are not acquainted: from those which we have cited, the reader may see the very great progress which the actuary's tables have made in the last twenty years.

We shall mention a literary curiosity of the subject, the spurious edition of Francis Baily's celebrated work[†] on Life Assurance: the only instance in modern times, we believe, in which a heavy work of algebra and tables has been *counterfeited*. The genuine work, though never out of reputation, was soon out of print: and such copies as were sold by auction fetched enormous prices. About the year 1850, copies of the work, in appearance, were offered at the assurance offices at less than a quarter of the old auction prices: which were discovered on examination to be spurious. The type, paper, &c., of the genuine work had been imitated almost to the smallest points; but the careful supervision which Baily always gave to details, and the excellent performance of his printer, could not be imitated. Those who do not know the original edition will immediately detect the spurious edition by an inverted δ being always used for the letter ρ. Shabby as the undertaking was, it invaded no copyright: and as no one now much wants Baily's work for the *tables*, so that it matters less whether these be accurately reprinted or not, it must be granted that the still valuable part of Baily's work has been made more accessible, and therefore more useful. We are of opinion that an edition of the work, with no more than specimens of the tables, and notes, critical, historical, and prospective, would command circulation.

The railroads have created a demand for tables of the cubic yards in cuttings, embankments, &c. Of these we select three, of extreme and mean sizes. First, 'A general sheet-table, &c.,' on one side of one sheet, by F. Bashforth, M.A., very efficient for its size. Secondly, 'Tables for . . . . earthwork of Railways,' 1847, by C. K. Sibley and W. Rutherford; a collection of sheets, with flexible cover, small folio. Thirdly, the second edition, 'Tables for facilitating the calculation of earthwork,' by Sir John Macneill, Dublin, 1846, an 8vo. volume of 368 pages. We describe what we have by us, not knowing what editions may now be current, or what other works there may be.

The practice of stereotyping tables is one which should be strongly enforced, if it were not that publishers seem now to be aware of its importance. A second edition derives no authority from the goodness of the first, because the printer, who is, as already observed, as important a person as the author in the matter of tables, has again stepped between the latter and the public. In reading the proofs of important tables, it is desirable that three persons should be employed, one to read from the manuscript, the others to watch two separate proofs, without communication with each other, as done in the Nautical Almanac office. The strictest investigation should take place in the proof which is taken from the stereotype, ordinary pains being taken with the previous proofs. Persons who have to correct the proofs of tables alone should bring the manuscript as near as possible to the proof by folding it conveniently: even if the folds were altered after every two or three lines, so as always to have both manuscript and proof under the eye in one position, it would not give more trouble than would be well repaid. Double figures should be particularly attended to; no mistake is so likely to be made, either by the compositor or the reader, as 744 for 774, and the like. This, and misplacing the order of the figures, as 012 for 102, are the things which it is most difficult to avoid. Again, of the two things under examination, manuscript and proof, the more difficult one should be looked at first, for the mind is apt to allow knowledge derived from the more easy to give help in interpreting the more difficult. Thus, if the type be harder to read than the manuscript (a very common thing with thick even-sized numerals), make out the proof first, and then look at the manuscript; and *vice versâ*. If two readings be given, vary the mode; the following may for instance be the plan adopted: if the manuscript column contain *a*, *b*, *c*, &c., and the printed column A, B, C, &c., look at *a*, compare it with A, then at B, compare it with *b*,

---

to the undertaking, would not have ventured to propose such an unheard-of extent of tables; and this extent was proposed to him, and not by him, during the actual progress of the work. It was Mr. Jones who first proposed a large extension of existing means, and the Society asked for more.

[*] In our first article appears the following: "The work of Mr. Jones on *Life Annuities*, in the 'Library of Useful Knowledge,' which is now brought nearly to a close, contains more tables than the old standard works all put together, and is the first in which extensive tables for what is called *Barrett's Method* are furnished, both for one and two lives."

[†] Mr. Sang arranged the types in the boxes, before using them, with all the care of composition, and set them up in the boxes all in one way. He then set the types for printing from with his own hands. The second volume was treated in the same way by his computers. A computer can set up the types from the original calculations; and thus the labour and risk of re-writing are avoided. The time of setting up was ultimately reduced to not much more than what would have been required for re-writing the manuscript; the computers, after very little practice, were able to outstrip the speed of ordinary compositors. The only predecessor of Mr. Sang in this matter that we know of is Mœstlinus, who, in 1596, while superintending some printing for Kepler, writes that the tables have been very badly described (as to structure), and adds, *Hinc nullus typothetarum operi manus admovere potest: Ipse cogor typothetam agere.*

[‡] This form is impracticable. The fifteen sheets joined together make a table of 9½ feet by 4¾ feet. This is too much, even for the wall of an office. We examined the table by nailing the sheets against the front of a bookcase, and using a step-ladder, as Gulliver did when pursuing his studies at Brobdingnag.

[*] The tables formed on Barrett's method are variously described as *Barrett's* tables, *Davies's* tables (G. Davies was an improver), *D and N* tables, and *Commutation* tables.

[†] In 1848–9, something more than a dozen copies of Baily's work came into the hands of Mr. Maynard, mathematical bookseller, slightly imperfect. The missing parts were reprinted (pp. 305–320 and 545–552). These copies were in Baily's hands till his death: and when the book was selling by auction at and over five guineas, his friends applied to him again and again to have the deficiencies made good and the books put into circulation; but they never could prevail.

then at *c*, compare it with C, and so on; the order of inspection being *a*A, B*b*, *c*C, D*d*, &c. Some persons examine best by the eye alone, others by the ear also, repeating aloud. Each one must ascertain for himself which practice is best for him; but whatever it may be, it should be varied. Alteration of position, motion of the hand or foot occasionally to mark the transitions, change of the tone of repeating, &c., are useful: it is hardly credible, to those who have not tried, how much the perceptions are dulled by the monotonous comparison of one column of figures with another, or how many and how gross errors both eye and ear, when tired, will suffer to pass. Persons who are not much used to this labour might very well proceed as follows. Let them request the printer to make, at his own discretion, a certain number, say three, of mistakes (author-traps) in every page, carefully registering them, but not on the manuscript. The author may then be certain that he ought to detect three mistakes in every page, and will know that he has been careless if he have not that number at least. But at the same time, an author who has not reason for confidence in himself, may very safely leave good manuscript tables entirely to the printer, if he make the latter understand that he does not intend to correct till all is printed off, and will require every page containing an error to be cancelled. No good printer would now refuse to engage to furnish a fac-simile of a manuscript, on the simple condition of being allowed to refer to the author for decision as to any doubtful word or figure in the writing; and the accuracy with which the first-rate London[*] printers turn out their proofs, even where the manuscript is criminally bad, is surprising. We have frequently looked at page after page of table-matter more times than we should otherwise have thought necessary, merely because the total absence of detected error left it an unsettled point whether it was the excellence of the proof, or a temporary suspension of our own quickness of perception, which caused the absence in question.

Catalogues of tables (separate) may be seen in the catalogue of the Royal Society's Library; in Murhard's 'Bibl. Math.;' in Lalande's 'Bibl. Astron.' (in virtue of the index); but there is nothing approaching to even a moderately perfect catalogue.

* * *

In the preceding article we have described, we believe, all the tables of note, whether in history or practice, so far as general tables of pure mathematics are concerned. We have omitted those which relate only to astronomy, life contingencies, or any other special application of mathematics. As the article stood in the 'Penny Cyclopædia,' we had brought forward about 318 tables, of which 221 had been taken from actual inspection, and the remainder from various authorities, very few indeed from one only. In Lalande's 'Bibliographie Astronomique' there are 208 tables mentioned, *including astronomical ones.* In the printed catalogue of the Royal Society's Library the entries under tables, of every sort, mathematics, astronomy, navigation, geography, meteorology, &c., are 536 in number, including from the merest tide-table for one year up to the largest body of logarithms. And upon looking at the appearances which the different catalogues present, we do not find one in which 200, or even 100, tables of pure mathematics are mentioned as having undergone the actual inspection of the compiler. In the present article we have given about 457 tables, of which 332 are from actual inspection. It would not, then, we suspect, be a very extensive undertaking to make as complete a list of tables of all kinds as can now be recovered; and the undertaker of it might expect to be able to verify about two out of three from inspection.

In the present article some additions have been made, both of tables and of facts alluding to tables already inserted, and several corrections. We have not made any effort to include all the tables of the last few years, preferring to direct our chief attention to the improvement of the antiquarian part of our task. To this end we have examined anew all the old tables which we could conveniently see. In reviewing our work, we find that we have sometimes spoken of the *decimal places* in a table, and sometimes of the *radius* to which it is constructed; but we do not mean that the old tables had decimal places, properly so called. We must also remind the reader that this article is not *bibliographical;* our affair is not with books as books, but with tables as tables. Accordingly, the descriptions of books are not fully given: and their contents, except so far as they are the tables spoken of, are wholly unnoticed.

TABLE, ROUND. The most famous Round Table is that of King Arthur, which is said in the old romances to have been constructed by the wizard Merlin for Uther Pendragon, Arthur's father, from whom it passed into the possession of Leodigan, or Leodegrance, king of Camelard, or Carmalide, whose capital was Carshaise, and then came to Arthur as the portion of his wife Guenevre, daughter of that monarch. The romance of the 'Mort d'Arthur' says that Merlin made it "in token of the roundness of the world;" according to the metrical romance of Merlin, it was made in imitation of one which had been set up by Joseph of Arimathea in commemoration of that at which the twelve apostles ate the last supper with their divine Master. The Round Table is not mentioned at all by Geoffrey of Monmouth, either in his 'Chronicle,' or in his 'Life of Merlin' in Latin verse; but it is noticed by his contemporary Wace, in his metrical 'Roman de Rois d'Angleterre.' The Round Table was intended, to quote the analysis of the romance of Merlin given by Ellis ('Specimens of Early English Romances,' i.), "to assemble the best knights in the world." There are different accounts of the number of the Knights of the Round Table, which indeed appears not to have been always the same. The romance of Merlin, which states that Uther had no power to fill all the seats, makes that king nevertheless to have nominated 250 knights, and these are also spoken of as forming the number of the order under Leodegrance. The 'Mort d'Arthur' makes Leodegrance say, in surrendering it to Arthur, "I shall give him the Table Round, the which Uther Pendragon gave me, and when it is full complete, there is a hundred knights and fifty; and, as for an hundred good knights, I have myself, but I lack fifty, for so many have been slain in my days." Of the fifty knights that were wanted, Merlin was at the moment only able to find twenty-eight for Arthur; but some were added afterwards. Other accounts again make the complete number under Arthur to have been only a hundred.

It is asserted by some of the chroniclers that some time before Edward III. instituted the order of the Garter, he established in the castle of Windsor a fraternity of twenty-four knights, and erected for them a round table, in imitation of that of Arthur, with a chamber in which it was placed, in what is yet known as the Round Tower. Bishop Percy, in his 'Reliques of Antient English Poetry,' remarks "that the round table was not peculiar to the reign of King Arthur, but was common in all the ages of chivalry. The proclaiming a great tournament (probably with some peculiar solemnities) was called holding a Round Table." And he quotes a passage from Dugdale, in which that learned antiquary, describing a tournament held at Kenilworth by Roger de Mortimer, in the reign of Edward I., says, "Then began the Round Table, so called by reason that the place wherein they practised those feats was environed with a strong wall made in a round form." Percy adds that Matthew Paris frequently calls jousts and tournaments *Hastiludia Mensæ Rotundæ.* These round tables were probably a contrivance on the principle of the modern Round Robin, to prevent any dispute about precedency. There are several circular elevations in different parts of England which are still called Arthur's Round Tables.

TABLES, TWELVE. [TWELVE TABLES.]

TACK is the technical term in Scotland for a lease, whether of lands or edifices; the rent is called the tack-duty, and the tenant the tacksman. The Scotch lease, however long its duration, is purely a contract, and does not partake—at least in questions between landlord and tenant—of the peculiarities of the feudal system. In early times it is possible to trace something like an inferior system of vassalage in the nature of the agriculturist's tenure; but as all descriptions of permanent estates could be constituted in the land by the adaptation of the feudal usages, there was no temptation to convert the contract for the limited occupation and use of the land into a means of constituting a semi-proprietary right in it. The system of leases accordingly, as one of mere letting and hiring, took its principles from the Roman contract of *locatio conductio*, the right of the lessee or tacksman being so purely personal that it was ineffectual against a party acquiring the lands by purchase from the lessor. Leasehold rights, however, in questions of succession, and in the form of attachment, employable by creditors, have by usage come into the position of real or heritable property, and may now be registered and transferred by the appropriate forms of transfer like estates in fee simple.

Writing is necessary to constitute a lease, although possession during the part that may remain over a year begun, may be held as a right from sufferance and acquiescence in its commencement. Without writing the term is for a year only.

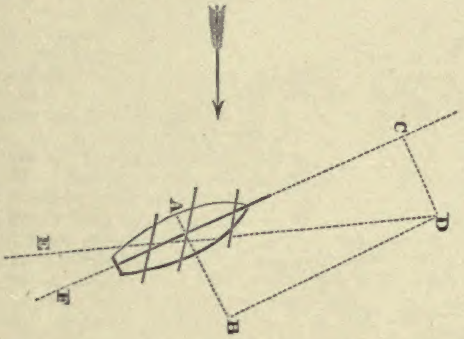
TACKING. The evolutions of a ship when contending with an adverse wind are called tacking; and the course upon which a ship lies is called its "tack," and whether the wind blow on the starboard- or port-side, these are called starboard or port tacks. In endeavouring to move a ship under sail towards the point from which the wind blows, she must necessarily be close hauled, that is, her sails must be so braced as to enable her to proceed as near the wind as possible.

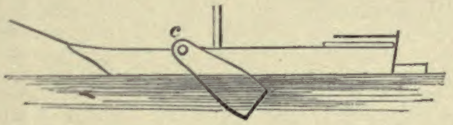
We may illustrate the operation of tacking by reference to a similar movement in ourselves, whether on foot or horseback, when we mount a steep incline on shore; for, instead of facing the inclination of the hill in its abruptness, we sidle along upwards in a zig-zag direction until the summit is reached,—and thus it is with tacking at sea; where, however, we use horizontal angles instead of the vertical ones on land.

---

[*] This was first published in 1842. In the spring of 1845, the Nautical Almanac of the year was nearly exhausted, and it was necessary to reprint it with the utmost speed. The Nautical Almanac contains more than 500 large octavo pages of numerical tables. Clowes and Son, all revision being left to their own readers, performed the task in seventeen *working* days, from the commencement of the composition to the delivery in sheets. The accuracy of this reprint was never impeached. A printer who was engaged upon an article in which the above statement was made, assured the author that he must be wrong, that the reprint was made from standing type, as was proved by the revision being intrusted to the printer: on which proper attestations were procured from Clowes and Son and their overseers, and these we have seen. Even printers, when their work is all of the ordinary kind, are not, it should seem, aware of the confidence due to those who are habitually concerned with such things as tables. This reprint, when it came to be examined, had only thirty-three errata. The necessity occurred again in 1846, and, as appears in the advertisement to the second edition of that work, the reprint was fully done in *sixteen* working days. Subsequent revision detected only twenty-two *errata*, seven of which were in *some copies only*, that is, due to hurried press-work. There was then perceptible progress, both in speed and accuracy.

The motion of a ship in thus beating to windward (as the whole evolution is called) is considerably affected by the form of the ship herself; for barges, and flat or round-bottom vessels make great leeway, or are driven bodily from the wind, and the actual course sailed is upon a line which is the resultant of two forces. For supposing the wind to be acting in the direction indicated by the arrow in the diagram, its power upon the mass of broadside and sails will have a tendency to drive it from A towards B (this is called leeway), while the action of the sails in their obliquity to the keel drives the body also forward in the line of keel A C. Now compounding these two forces, A B and C D, we have the parallelogram A D as the resultant, while the amount of leeway would be measured by A B, and its angle would be E A F. Hence tacking is more advantageous to sharp-bottomed vessels with a rising floor like yachts, cutters, &c., as they offer more vertical resistance to the water in arresting the lateral drift A B. Vessels having no keel or deadwood are generally furnished with what is called a "lee-board," which working on a strong pin, as at C in the figure, is let down below the bottom on the lee side to prevent too much leeway when tacking to windward.





In order to very briefly explain the operation of tacking (or as it is also called "heaving about"), suppose the figure below to represent a ship at *a*, beating towards the direction of the wind *x*, and close hauled on the port tack accordingly, the tiller is put over towards *y* ("hard a-lee"), which causes the rudder to bring the ship's head to wind, as at *b*, or throws her into "stays;" just before she reaches this position, the afteryards (on the main and mizen masts) are hauled aback and then braced as at *c*, and as soon as the ship's head is found to be about five points from the wind the head yards are braced round likewise, and the ship fills with the wind upon the starboard side, as seen at *d*, and she is now on the starboard tack. It is at times a perilous evolution, and if there be much sea on is found impracticable. To insure success however under ordinary circumstances, the helmsman just previously keeps the sails "clean full" (as the expression is), lest the ship's velocity be insufficient to bring her head to wind; if it be so, her head "falls off" again, and she is said to have *missed stays;* this is frequently caused by the helmsman neglecting to shift the helm when the ship acquires stern-way. When, from having lost all velocity, she will neither stay nor fall off, she is said to be "jammed up in the wind," or "in irons," the remedy being to brace the head-yards aback and "pay off." If such happen when too near shore the danger is imminent. (VEERING.)
